Description

Overview of the psych package.

The psych package has been developed at Northwestern University to include functions most useful for personality and psychological research. Some of the functions (e.g., \texttt{read.file}, \texttt{read.clipboard}, \texttt{describe}, \texttt{pairs.panels}, \texttt{error.bars} and \texttt{error.dots}) are useful for basic data entry and descriptive analyses. Use \texttt{help(package=“psych“)} or \texttt{objects(“package:psych“)} for a list of all functions. Three vignettes are included as part of the package. The intro vignette tells how to install psych and overview vignette provides examples of using psych in many applications. In addition, there are a growing set of tutorials available on the \url{https://personality-project.org/r} webpages.

A companion package \texttt{psychTools} includes larger data set examples and one more vignette.

Psychometric applications include routines (\texttt{fa} for maximum likelihood (fm=“mle”), minimum residual (fm=“minres”), minimum rank (fm=minrank) principal axes (fm=“pa”) and weighted least squares (fm=“wls”) factor analysis as well as functions to do Schmid Leiman transformations (\texttt{schmid}) to transform a hierarchical factor structure into a bifactor solution. Principal Components Analysis (\texttt{pca}) is also available. Rotations may be done using factor or components transformations to a target matrix include the standard Promax transformation (\texttt{Promax}), a transformation to a cluster target, or to any simple target matrix (\texttt{target.rot}) as well as the ability to call many of the GPArotation functions (e.g., oblimin, quartimin, varimax, geomin, ...). Functions for determining the number of factors in a data matrix include Very Simple Structure (\texttt{VSS}) and Minimum Average Partial correlation (\texttt{MAP}).

An alternative approach to factor analysis is Item Cluster Analysis (\texttt{ICLUST}). This function is particularly appropriate for exploratory scale construction.

There are a number of functions for finding various reliability coefficients. These include the traditional \texttt{alpha} (found for multiple scales and with more useful output by \texttt{scoreItems}, \texttt{score.multiple.choice}), \texttt{beta} (\texttt{ICLUST}) and both of McDonald’s omega coefficients (\texttt{omega}, \texttt{omegaSem} and \texttt{omega.diagram}) as well as Guttman’s six estimates of internal consistency reliability (\texttt{guttman}) and the six measures of Intraclass correlation coefficients (\texttt{ICC}) discussed by Shrout and Fleiss are also available.

Multilevel analyses may be done by \texttt{statsBy} and \texttt{multilevel.reliability}. 

\textbf{Index} 383
The `scoreItems` and `score.multiple.choice` functions may be used to form single or multiple scales from sets of dichotomous, multilevel, or multiple choice items by specifying scoring keys. `scoreOverlap` correct interscale correlations for overlapping items, so that it is possible to examine hierarchical or nested structures.

Scales can be formed that best predict (after cross validation) particular criteria using `bestScales` using unit weighted or correlation weights. This procedure, also called the BISCUIT algorithm (Best Items Scales that are Cross validated, Unit weighted, Informative, and Transparent) is a simple alternative to more complicated machine learning algorithms.

Additional functions make for more convenient descriptions of item characteristics include 1 and 2 parameter Item Response measures. The `tetrachoric`, `polychoric` and `irt.fa` functions are used to find 2 parameter descriptions of item functioning. `scoreIrt`, `scoreIrt.1pl` and `scoreIrt.2pl` do basic IRT based scoring.

A number of procedures have been developed as part of the Synthetic Aperture Personality Assessment (SAPA [https://sapa-project.org](https://sapa-project.org)) project. These routines facilitate forming and analyzing composite scales equivalent to using the raw data but doing so by adding within and between cluster/scale item correlations. These functions include extracting clusters from factor loading matrices (`factor2cluster`), synthetically forming clusters from correlation matrices (`cluster.cor`), and finding multiple (`setCor`) and partial (`partial.r`) correlations from correlation matrices. `setCor` and `mediate` meet the desire to do regressions and mediation analysis from either raw data or from correlation matrices. If raw data are provided, these functions can also do moderation analyses.

Functions to generate simulated data with particular structures include `sim.circ` (for circumplex structures), `sim.item` (for general structures) and `sim.congeneric` (for a specific demonstration of congeneric measurement). The functions `sim.congeneric` and `sim.hierarchical` can be used to create data sets with particular structural properties. A more general form for all of these is `sim.structural` for generating general structural models. These are discussed in more detail in the vignette (`psych_for_sem`).

Functions to apply various standard statistical tests include `p.rep` and its variants for testing the probability of replication, `r.con` for the confidence intervals of a correlation, and `r.test` to test single, paired, or sets of correlations.

In order to study diurnal or circadian variations in mood, it is helpful to use circular statistics. Functions to find the circular mean (`circadian.mean`), circular (phasic) correlations (`circadian.cor`) and the correlation between linear variables and circular variables (`circadian.linear.cor`) supplement a function to find the best fitting phase angle (`cosinor`) for measures taken with a fixed period (e.g., 24 hours).

A dynamic model of personality and motivation (the Cues-Tendency-Actions model) is include as `cta`.

A number of useful helper functions allow for data input (`read.file`), and data manipulation `cs` and `dfOrder`.

The most recent development version of the package is always available for download as a source file from the repository at the PMC lab: `install.packages("psych", repos = "https://personality-project.org/r/", type="source")`. This will provide the most recent version for PCs and Macs.

**Details**

Three vignettes (overview.pdf and psych_for_sem.pdf) are useful introductions to the package. They may be found as vignettes in R or may be downloaded from [https://personality-project.org/r/psych/intro.pdf](https://personality-project.org/r/psych/intro.pdf) [https://personality-project.org/r/psych/overview.pdf](https://personality-project.org/r/psych/overview.pdf) and [https:](https:).
In addition, there are a number of "HowTo"s available at https://personality-project.org/r/

The more important functions in the package are for the analysis of multivariate data, with an emphasis upon those functions useful in scale construction of item composites. However, there are a number of very useful functions for basic data manipulation including read.file, read.clipboard, describe, pairs.panels, error.bars and error.dots which are useful for basic data entry and descriptive analyses.

When given a set of items from a personality inventory, one goal is to combine these into higher level item composites. This leads to several questions:

1) What are the basic properties of the data? describe reports basic summary statistics (mean, sd, median, mad, range, minimum, maximum, skew, kurtosis, standard error) for vectors, columns of matrices, or data.frames. describeBy provides descriptive statistics, organized by one or more grouping variables. statsBy provides even more detail for data structured by groups including within and between correlation matrices, ICCs for group differences, as well as basic descriptive statistics organized by group.

pairs.panels shows scatter plot matrices (SPLOMs) as well as histograms and the Pearson correlation for scales or items. error.bars will plot variable means with associated confidence intervals. errorCircles will plot confidence intervals for both the x and y coordinates. corr.test will find the significance values for a matrix of correlations. error.dots creates a dot chart with confidence intervals.

2) What is the most appropriate number of item composites to form? After finding either standard Pearson correlations, or finding tetrachoric or polychoric correlations, the dimensionality of the correlation matrix may be examined. The number of factors/components problem is a standard question of factor analysis, cluster analysis, or principal components analysis. Unfortunately, there is no agreed upon answer. The Very Simple Structure (VSS) set of procedures has been proposed as an answer to the question of the optimal number of factors. Other procedures (VSS.scree, VSS.parallel, fa.parallel, and MAP) also address this question. nfactors combine several of these approaches into one convenient function. Unfortunately, there is no best answer to the problem.

3) What are the best composites to form? Although this may be answered using principal components (principal), principal axis (factor.pa) or minimum residual (factor.minres) factor analysis (all part of the fa function) and to show the results graphically (fa.diagram), it is sometimes more useful to address this question using cluster analytic techniques. Previous versions of ICLUST (e.g., Revelle, 1979) have been shown to be particularly successful at forming maximally consistent and independent item composites. Graphical output from ICLUST.graph uses the Graphviz dot language and allows one to write files suitable for Graphviz. If Rgraphviz is available, these graphs can be done in R.

Graphical organizations of cluster and factor analysis output can be done using cluster.plot which plots items by cluster/factor loadings and assigns items to that dimension with the highest loading.

4) How well does a particular item composite reflect a single construct? This is a question of reliability and general factor saturation. Multiple solutions for this problem result in (Cronbach’s) alpha (alpha, scoreItems), (Revelle’s) Beta (ICLUST), and (McDonald’s) omega (both omega hierarchical and omega total). Additional reliability estimates may be found in the guttmann function.

This can also be examined by applying irt.fa Item Response Theory techniques using factor analysis of the tetrachoric or polychoric correlation matrices and converting the results into the standard two parameter parameterization of item difficulty and item discrimination. Information functions for the items suggest where they are most effective.

5) For some applications, data matrices are synthetically combined from sampling different items for different people. So called Synthetic Aperture Personality Assessment (SAPA) techniques al-
low the formation of large correlation or covariance matrices even though no one person has taken all of the items. To analyze such data sets, it is easy to form item composites based upon the covariance matrix of the items, rather than original data set. These matrices may then be analyzed using a number of functions (e.g., \texttt{cluster.cor}, \texttt{fa}, \texttt{ICLUST}, \texttt{principal}, \texttt{mat.regress}, and \texttt{factor2cluster}).

6) More typically, one has a raw data set to analyze. \texttt{alpha} will report several reliability estimates as well as item-whole correlations for items forming a single scale, \texttt{score.items} will score data sets on multiple scales, reporting the scale scores, item-scale and scale-scale correlations, as well as coefficient alpha, alpha-1 and G6+. Using a ‘keys’ matrix (created by \texttt{make.keys} or by hand), scales can have overlapping or independent items. \texttt{score.multiple.choice} scores multiple choice items or converts multiple choice items to dichotomous (0/1) format for other functions.

7) In addition to classical test theory (CTT) based scores of either totals or averages, 1 and 2 parameter IRT based scores may be found with \texttt{scoreIrt.1pl}, \texttt{scoreIrt.2pl} or more generally \texttt{scoreIrt}. Although highly correlated with CTT estimates, these scores take advantage of different item difficulties and are particularly appropriate for the problem of missing data.

8) If the data has a multilevel structure (e.g, items nested within time nested within subjects) the \texttt{multilevel.reliability} aka \texttt{mlr} function will estimate generalizability coefficients for data over subjects, subjects over time, etc. \texttt{mlPlot} will provide plots for each subject of items over time. \texttt{mlArrange} takes the conventional wide output format and converts it to the long format necessary for some multilevel functions. Other functions useful for multilevel data include \texttt{statsBy} and \texttt{faBy}.

An additional set of functions generate simulated data to meet certain structural properties. \texttt{sim.anova} produces data simulating a 3 way analysis of variance (ANOVA) or linear model with or with out repeated measures. \texttt{sim.item} creates simple structure data, \texttt{sim.circ} will produce circumplex structured data, \texttt{sim.dichot} produces circumplex or simple structured data for dichotomous items. These item structures are useful for understanding the effects of skew, differential item endorsement on factor and cluster analytic solutions. \texttt{sim.structural} will produce correlation matrices and data matrices to match general structural models. (See the vignette).

When examining personality items, some people like to discuss them as representing items in a two dimensional space with a circumplex structure. Tests of circumplex fit \texttt{circ.tests} have been developed. When representing items in a circumplex, it is convenient to view them in polar coordinates.

Additional functions for testing the difference between two independent or dependent correlation \texttt{r.test}, to find the \texttt{phi} or \texttt{Yule} coefficients from a two by table, or to find the confidence interval of a correlation coefficient.

Many data sets are included: \texttt{bfi} represents 25 personality items thought to represent five factors of personality, \texttt{ability} has 14 multiple choice iq items. \texttt{sat.act} has data on self reported test scores by age and gender. \texttt{galton} Galton’s data set of the heights of parents and their children. \texttt{peas} recreates the original Galton data set of the genetics of sweet peas. \texttt{heights} and \texttt{cubits} provide even more Galton data, \texttt{vegetables} provides the Guilford preference matrix of vegetables. \texttt{cities} provides airline miles between 11 US cities (demo data for multidimensional scaling).

Package:      psych

Data reduction through cluster and factor analysis

fa
factor.pa
factor.minres
factor.wls
fa.graph
fa.diagram
fa.sort
fa.extension
principal
fa.parallel
fa.parallel.poly
factor.scores
guttman
irt.fa
iclust
ICLUST.graph
ICLUST.rgraph
kaiser
polychoric
Find the polychoric correlations for items and find item thresholds
poly.mat
Find the polychoric correlations for items (uses J. Fox’s hetcor)
omega
Calculate the omega estimate of factor saturation (requires the GPArotation package)
omega.graph
Draw a hierarchical or Schmid Leiman orthogonalized solution (uses Rgraphviz)
partial.r
Partial variables from a correlation matrix
predict
Predict factor/component scores for new data
schmid
Apply the Schmid Leiman transformation to a correlation matrix
score.items
Combine items into multiple scales and find alpha
score.multiple.choice
Combine items into multiple scales and find alpha and basic scale statistics
set.cor
Find Cohen’s set correlation between two sets of variables
smc
Find the Squared Multiple Correlation (used for initial communality estimates)
tetrachoric
Find tetrachoric correlations and item thresholds
polyserial
Find polyserial and biserial correlations for item validity studies
mixed.cor
Form a correlation matrix from continuous, polytomous, and dichotomous items
VSS
Apply the Very Simple Structure criterion to determine the appropriate number of factors.
VSS.parallel
Do a parallel analysis to determine the number of factors for a random matrix
VSS.plot
Plot VSS output
VSS.scree
Show the scree plot of the factor/principal components
MAP
Apply the Velicer Minimum Absolute Partial criterion for number of factors

Functions for reliability analysis (some are listed above as well).

alpha
Find coefficient alpha and Guttman Lambda 6 for a scale (see also score.items)
guttman
8 different measures of reliability (6 from Guttman (1945))
omega
Calculate the omega estimates of reliability (requires the GPArotation package)
omegaSem
Calculate the omega estimates of reliability using a Confirmatory model (requires the sem package)
ICC
Intraclass correlation coefficients
score.items
Combine items into multiple scales and find alpha
glb.algebraic
The greates lower bound found by an algebraic solution (requires Rsdp). Written by Andreas Moeltner

Procedures particularly useful for Synthetic Aperture Personality Assessment

alpha
Find coefficient alpha and Guttman Lambda 6 for a scale (see also score.items)
bestScales
A bootstrap aggregation function for choosing most predictive unit weighted items
make.keys
Create the keys file for score.items or cluster.cor
correct.cor
Correct a correlation matrix for unreliability
count.pairwise
Count the number of complete cases when doing pair wise correlations
cluster.cor
Find correlations of composite variables from larger matrix
cluster.loadings
Find correlations of items with composite variables from a larger matrix
eigen.loadings
Find the loadings when doing an eigen value decomposition
fa
Do a minimal residual or principal axis factor analysis and estimate factor scores
fa.extension
Extend a factor analysis to a set of new variables
factor.pa
Do a Principal Axis factor analysis and estimate factor scores
factor2cluster
extract cluster definitions from factor loadings
factor.congruence
Factor congruence coefficient
factor.fit
How well does a factor model fit a correlation matrix
factor.model
Reproduce a correlation matrix based upon the factor model
factor.residuals
Fit = data - model
factor.rotate
“hand rotate” factors
guttman 8 different measures of reliability
mat.regress standardized multiple regression from raw or correlation matrix input
polyserial polyserial and biserial correlations with massive missing data
tetrachoric Find tetrachoric correlations and item thresholds

Functions for generating simulated data sets

sim The basic simulation functions
sim.anova Generate 3 independent variables and 1 or more dependent variables for demonstrating ANOVA and lm designs
sim.circ Generate a two dimensional circumplex item structure
sim.congeneric Generate a one factor congeneric reliability structure
sim.minor Simulate nfact major and nvar/2 minor factors
sim.structural Generate a multifactorial structural model
sim.irt Generate data for a 1, 2, 3 or 4 parameter logistic model
sim.VSS Generate simulated data for the factor model
phi.demo Create artificial data matrices for teaching purposes
sim.hierarchical Generate simulated correlation matrices with hierarchical or any structure
sim.spherical Generate three dimensional spherical data (generalization of circumplex to 3 space)

Graphical functions (require Rgraphviz) – deprecated

structure.graph Draw a sem or regression graph
fa.graph Draw the factor structure from a factor or principal components analysis
omega.graph Draw the factor structure from an omega analysis(either with or without the Schmid Leiman transformation)
ICLUST.graph Draw the tree diagram from ICLUST

Graphical functions that do not require Rgraphviz

diagram A general set of diagram functions.
structure.diagram Draw a sem or regression graph
fa.diagram Draw the factor structure from a factor or principal components analysis
omega.diagram Draw the factor structure from an omega analysis(either with or without the Schmid Leiman transformation)
ICLUST.diagram Draw the tree diagram from ICLUST
plot.psych A call to plot various types of output (e.g. from irt.fa, fa, omega, iclust
cor.plot A heat map display of correlations
spider Spider and radar plots (circular displays of correlations)

Circular statistics (for circadian data analysis)

circadian.cor Find the correlation with e.g., mood and time of day
circadian.linear.cor Correlate a circular value with a linear value
circadian.mean Find the circular mean of each column of a a data set
### cosinor
Find the best fitting phase angle for a circular data set

#### Miscellaneous functions

- **comorbidity**: Convert base rate and comorbidity to phi, Yule and tetrachoric
- **df2latex**: Convert a data.frame or matrix to a LaTeX table
- **dummy.code**: Convert categorical data to dummy codes
- **fisherz**: Apply the Fisher r to z transform
- **fisherz2r**: Apply the Fisher z to r transform
- **ICC**: Intraclass correlation coefficients
- **cortest.mat**: Test for equality of two matrices (see also cortest.normal, cortest.jennrich)
- **cortest.bartlett**: Test whether a matrix is an identity matrix
- **paired.r**: Test for the difference of two paired or two independent correlations
- **r.con**: Confidence intervals for correlation coefficients
- **r.test**: Test of significance of r, differences between rs.
- **p.rep**: The probability of replication given a p, r, t, or F
- **phi**: Find the phi coefficient of correlation from a 2 x 2 table
- **phi.demo**: Demonstrate the problem of phi coefficients with varying cut points
- **phi2poly**: Given a phi coefficient, what is the polychoric correlation
- **phi2poly.matrix**: Given a phi coefficient, what is the polychoric correlation (works on matrices)
- **polar**: Convert 2 dimensional factor loadings to polar coordinates
- **scaling.fits**: Compares alternative scaling solutions and gives goodness of fits
- **scrub**: Basic data cleaning
- **tetrachor**: Finds tetrachoric correlations
- **thurstone**: Thurstone Case V scaling
- **tr**: Find the trace of a square matrix
- **wkappa**: weighted and unweighted versions of Cohen’s kappa
- **Yule**: Find the Yule Q coefficient of correlation
- **Yule.inv**: What is the two by two table that produces a Yule Q with set marginals?
- **Yule2phi**: What is the phi coefficient corresponding to a Yule Q with set marginals?
- **Yule2teta**: Convert one or a matrix of Yule coefficients to tetrachoric coefficients.

#### Functions that are under development and not recommended for casual use

- **irt.item.diff.rasch**: IRT estimate of item difficulty with assumption that theta = 0
- **irt.person.rasch**: Item Response Theory estimates of theta (ability) using a Rasch like model

#### Data sets included in the psych or psychTools package

- **bfi**: represents 25 personality items thought to represent five factors of personality
- **Thurstone**: 8 different data sets with a bifactor structure
- **cities**: The airline distances between 11 cities (used to demonstrate MDS)
- **epi.bfi**: 13 personality scales
- **iqitems**: 14 multiple choice iq items
msq 75 mood items
sat.act Self reported ACT and SAT Verbal and Quantitative scores by age and gender
Tucker Correlation matrix from Tucker
galton Galton’s data set of the heights of parents and their children
heights Galton’s data set of the relationship between height and forearm (cubit) length
cubits Galton’s data table of height and forearm length
peas Galton’s data set of the diameters of 700 parent and offspring sweet peas
vegetables Guilford’s preference matrix of vegetables (used for thurstone)

test.psych Run a test of the major functions on 5 different data sets. Primarily for development purposes. Although the output can be used as a demo of the various functions.

Note
Development versions (source code) of this package are maintained at the repository https://personality-project.org/r along with further documentation. Specify that you are downloading a source package.
Some functions require other packages. Specifically, omega and schmid require the GPArotation package, ICLUST.rgraph and fa.graph require Rgraphviz but have alternatives using the diagram functions. i.e.:

# test.psych()

alpha

Find two estimates of reliability: Cronbach's alpha and Guttman's Lambda 6.

Description

Internal consistency measures of reliability range from $\omega_h$ to $\alpha$ to $\omega_l$. This function reports two estimates: Cronbach's coefficient $\alpha$ and Guttman's $\lambda_6$. Also reported are item-whole correlations, $\alpha$ if an item is omitted, and item means and standard deviations.

Usage

alpha(x, keys=NULL, cumulative=FALSE, title=NULL, max=10, na.rm = TRUE, check.keys=FALSE, n.iter=1, delete=TRUE, use="pairwise", warnings=TRUE, n.obs=NULL, impute=NULL)

alpha.ci(alpha, n.obs, n.var=NULL, p.val=.05, digits=2)

Arguments

x A data.frame or matrix of data, or a covariance or correlation matrix
keys If some items are to be reversed keyed, then either specify the direction of all
        items or just a vector of which items to reverse
title Any text string to identify this run
cumulative should means reflect the sum of items or the mean of the items. The default
        value is means.
max the number of categories/item to consider if reporting category frequencies. De-
       faults to 10, passed to link{response.frequencies}
na.rm The default is to remove missing values and find pairwise correlations
check.keys if TRUE, then find the first principal component and reverse key items with
        negative loadings. Give a warning if this happens.
n.iter Number of iterations if bootstrapped confidence intervals are desired
delete Delete items with no variance and issue a warning
use Options to pass to the cor function: "everything", "all.obs", "complete.obs", 
        "na.or.complete", or "pairwise.complete.obs". The default is "pairwise"
warnings By default print a warning and a message that items were reversed. Suppress the
        message if warnings = FALSE
alpha The value to use for confidence intervals
n.obs If using correlation matrices as input, by specify the number of observations, we
        can find confidence intervals
impute How should we impute missing data? Not at all, medians, or means
n.var Number of items in the scale (to find r.bar)
p.val width of confidence interval (pval/2 to 1-p.val/2)
digits How many digits to use for alpha.ci
Details

Alpha is one of several estimates of the internal consistency reliability of a test. Surprisingly, more than a century after Spearman (1904) introduced the concept of reliability to psychologists, there are still multiple approaches for measuring it. Although very popular, Cronbach’s $\alpha$ (1951) underestimates the reliability of a test and overestimates the first factor saturation. $\alpha$ (Cronbach, 1951) is the same as Guttman’s $\lambda_3$ (Guttman, 1945) and may be found by

$$\lambda_3 = \frac{n}{n-1} \left(1 - \frac{tr(\bar{V})}{V_x}\right) = \frac{n}{n-1} \left(1 - \frac{tr(\bar{V})}{V_x}\right) = \alpha$$

Perhaps because it is so easy to calculate and is available in most commercial programs, alpha is without doubt the most frequently reported measure of internal consistency reliability. Alpha is the mean of all possible split half reliabilities (corrected for test length). For a unifactorial test, it is a reasonable estimate of the first factor saturation, although if the test has any microstructure (i.e., if it is “lumpy”) coefficients $\beta$ (Revelle, 1979; see ICLUST) and $\omega_h$ (see omega) are more appropriate estimates of the general factor saturation. $\omega_t$ (see omega) is a better estimate of the reliability of the total test.

Guttman’s Lambda 6 (G6) considers the amount of variance in each item that can be accounted for the linear regression of all of the other items (the squared multiple correlation or smc), or more precisely, the variance of the errors, $e_j^2$, and is

$$\lambda_6 = 1 - \frac{\sum e_j^2}{V_x} = 1 - \frac{\sum (1 - r_{smc}^2)}{V_x}.$$  

The squared multiple correlation is a lower bound for the item communality and as the number of items increases, becomes a better estimate.

G6 is also sensitive to lumpyness in the test and should not be taken as a measure of unifactorial structure. For lumpy tests, it will be greater than alpha. For tests with equal item loadings, alpha > G6, but if the loadings are unequal or if there is a general factor, G6 > alpha. alpha is a generalization of an earlier estimate of reliability for tests with dichotomous items developed by Kuder and Richardson, known as KR20, and a shortcut approximation, KR21. (See Revelle, in prep).

Alpha and G6 are both positive functions of the number of items in a test as well as the average intercorrelation of the items in the test. When calculated from the item variances and total test variance, as is done here, raw alpha is sensitive to differences in the item variances. Standardized alpha is based upon the correlations rather than the covariances.

A useful index of the quality of the test that is linear with the number of items and the average correlation is the Signal/Noise ratio where

$$s/n = \frac{n \bar{r}}{1 - \bar{r}}.$$  

(Cronbach and Gleser, 1964; Revelle and Condon (in press)).

More complete reliability analyses of a single scale can be done using the omega function which finds $\omega_h$ and $\omega_t$ based upon a hierarchical factor analysis.

Alternative functions score.items and cluster.cor will also score multiple scales and report more useful statistics. "Standardized" alpha is calculated from the inter-item correlations and will differ from raw alpha.

Four alternative item-whole correlations are reported, three are conventional, one unique. raw.r is the correlation of the item with the entire scale, not correcting for item overlap. std.r is the correlation of the item with the entire scale, if each item were standardized. r.drop is the correlation
of the item with the scale composed of the remaining items. Although each of these are conventional
statistics, they have the disadvantage that a) item overlap inflates the first and b) the scale is different
for each item when an item is dropped. Thus, the fourth alternative, r.cor, corrects for the item
overlap by subtracting the item variance but then replaces this with the best estimate of common
variance, the smc. This is similar to a suggestion by Cureton (1966).

If some items are to be reversed keyed then they can be specified by either item name or by item
location. (Look at the 3rd and 4th examples.) Automatic reversal can also be done, and this is
based upon the sign of the loadings on the first principal component (Example 5). This requires the
check.keys option to be TRUE. Previous versions defaulted to have check.keys=TRUE, but some
users complained that this made it too easy to find alpha without realizing that some items had been
reversed (even though a warning was issued!). Thus, I have set the default to be check.keys=FALSE
with a warning that some items need to be reversed (if this is the case). To suppress these warnings,
set warnings=FALSE.

Scores are based upon the simple averages (or totals) of the items scored. Thus, if some items are
missing, the scores reflect just the items answered. This is particularly problematic if using total
scores (with the cumulative=TRUE option). To impute missing data using either means or medians,
use the scoreItems function. Reversed items are subtracted from the maximum + minimum item
response for all the items.

When using raw data, standard errors for the raw alpha are calculated using equation 2 and 3 from
Duhhachek and Iacobucci (2004). This is problematic because some simulations suggest these
values are too small. It is probably better to use bootstrapped values.

alpha.ci finds confidence intervals using the Feldt et al. (1987) procedure. This procedure does
not consider the internal structure of the test the way that the Duhhachek and Iacobucci (2004) pro-
cedure does. That is, the latter considers the variance of the covariances, while the Feldt procedure
is based upon just the mean covariance.

Bootstrapped resamples are found if n.iter > 1. These are returned as the boot object. They may be
plotted or described. The 2.5% and 97.5% values are returned in the boot.ci object.

</tbody>
</table>
alpha

r.drop 
Item whole correlation for this item against the scale without this item

mean 
for data matrices, the mean of each item

sd 
For data matrices, the standard deviation of each item

response.freq 
For data matrices, the frequency of each item response (if less than 20)

scores 
Scores are by default simply the average response for all items that a participant took. If cumulative=TRUE, then these are sum scores. Note, this is dangerous if there are lots of missing values.

itemboot.ci 
The lower, median, and upper ranges of the 95% confidence interval based upon the bootstrap.

boot 
a 6 column by n.iter matrix of boot strapped resampled values

Unidim 
An index of unidimensionality

Fit 
The fit of the off diagonal matrix

Note

By default, items that correlate negatively with the overall scale will be reverse coded. This option may be turned off by setting check.keys = FALSE. If items are reversed, then each item is subtracted from the minimum item response + maximum item response where min and max are taken over all items. Thus, if the items intentionally differ in range, the scores will be off by a constant. See scoreItems for a solution.

Two item level statistics are worth comparing: the mean interitem r and the median interitem r. If these differ very much, that is a sign that the scale is not particularly homogeneous.

If the data have been preprocessed by the dplyr package, a strange error can occur. alpha expects either data.frames or matrix input. data.frames returned by dplyr have had three extra classes added to them which causes alpha to break. The solution is merely to change the class of the input to “data.frame”.

Two experimental measures of Goodness of Fit are returned in the output: Unidim and Fit. They are not printed or displayed, but are available for analysis. The first is an index of how well the modeled average correlations actually reproduce the original correlation matrix. The second is how well the modeled correlations reproduce the off diagonal elements of the matrix. Both are indices of squared residuals compared to the squared original correlations. These two measures are under development and might well be modified or dropped in subsequent versions.

Description
When doing regressions from the data or from a correlation matrix using setCor or doing a mediation analysis using link{mediate}, it is useful to compare alternative models. Since these are both regression models, the appropriate test is an Analysis of Variance. Similar tests, using Chi Square may be done for factor analytic models.
Usage
## S3 method for class 'psych'
anova(object,...)

Arguments
object  An object from setCor, mediate, omega, or fa.

Details
setCor returns the SE.residual and degrees of freedom. These are converted to SSR and then an analysis of variance is used to compare two (or more) models. For omega or fa the change in the ML chisquare statistic as a function of change in df is reported.

Value
An ANOVA table comparing the models.

Note
The code has been adapted from the anova.lm function in stats and the anova.sem by John Fox.

f2 <- fa(Thurstone,2, n.obs=213)
**Description**

In many fields, decisions and outcomes are categorical even though the underlying phenomenon are probably continuous. E.g. students are accepted to graduate school or not, they finish or not. X-Rays are diagnosed as patients having cancer or not. Outcomes of such decisions are usually labeled as Valid Positives, Valid Negatives, False Positives and False Negatives. In hypothesis testing, False Positives are known as Type I errors, while False Negatives are Type II errors. The relationship between these four cells depends upon the correlation between the decision rule and the outcome as well as the level of evidence needed for a decision (the criterion). Signal Detection Theory and Decision Theory have a number of related measures of performance (accuracy = VP + VN), Sensitivity (VP/(VP + FN)), Specificity (1 - FP), d prime (d'), and the area under the Response Operating Characteristic Curve (AUC). More generally, these are examples of correlations based upon dichotomous data. **AUC** addresses some of these questions.

**Usage**

```r
AUC(t=NULL,BR=NULL,SR=NULL,Phi=NULL,VP=NULL,labels=NULL,plot="b",zero=TRUE,correct=.5, col=c("blue","red"))
```

**Arguments**

- **t**: a 4 x 1 vector or a 2 x2 table of TP, FP, FN, TN values (see below) May be counts or proportions.
- **BR**: Base Rate of successful outcomes or actual symptom (if t is not specified)
- **SR**: Selection Rate for candidates or diagnoses (if t is not specified)
- **Phi**: The Phi correlation coefficient between the predictor and the outcome variable (if t is not specified)
- **VP**: The number of Valid Positives (selected applicants who succeed; correct diagnoses).(if t and Phi are not specified)
- **labels**: Names of variables 1 and 2
- **plot**: "b" (both), "d" (decision theory), "a" (auc), or "n" neither
- **zero**: If True, then the noise distribution is centered at zero
- **correct**: Cell values of 0 are replaced with correct. (See tetrachoric for a discussion of why this is needed.)
- **col**: The color choice for the VP and FP, defaults to =c("blue","red") but could be c("grey","black") if we want to avoid colors

**Details**

The problem of making binary decisions about the state of the world is ubiquitous. We see this in Null Hypothesis Significance Testing (NHST), medical diagnoses, and selection for occupations. Variously known as NHST, Signal Detection Theory, clinical Assessment, or college admissions, all of these domains share the same two x two decision task.
Although the underlying phenomena are probably continuous, a typical decision or diagnostic situation makes dichotomous decisions: Accept or Reject, correctly identified, incorrectly identified. In Signal Detection Theory, the world has two states: Noise versus Signal + Noise. The decision is whether there is a signal or not.

In diagnoses, it is whether to diagnose an illness or not given some noisy signal (e.g., an X-Ray, a set of diagnostic tests).

In college admissions, we accept some students and reject others. Four-Five years later we observe who "succeeds" or graduates.

All of these decisions lead to four cells based upon a two x two categorization. Given the true state of the world is Positive or Negative, and a rater assigns positive or negative ratings, then the resulting two by two table has True Positives and True Negatives on the diagonal and False Positives and False Negatives off the diagonal.

When expressed as percentages of the total, then Base Rates (BR) depend upon the state of the world, but Selection Ratios (SR) are under the control of the person making the decision and affect the number of False Positives and the number of Valid Positives.

Given a two x two table of counts or percentages

<table>
<thead>
<tr>
<th>Decide +</th>
<th>Decide -</th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>True +</td>
<td>VP</td>
<td>FN</td>
</tr>
<tr>
<td>True -</td>
<td>FP</td>
<td>VN</td>
</tr>
<tr>
<td>SR</td>
<td>1 - SR</td>
<td>(N)</td>
</tr>
</tbody>
</table>

Unfortunately, although this way of categorizing the data is typical in assessment (e.g., Wiggins 1973), and everything is expressed as percentages of the total, in some decision papers, VP are expressed as the ratio of VP to total positive decisions (e.g., Wickens, 1984). This requires dividing through by the column totals (and represented as VP* and FP* in the table below).

The relationships implied by these data can be summarized as a phi or tetrachoric correlation between the raters and the world, or as a decision process with several alternative measures: Sensitivity, Specificity, Accuracy, Area Under the Curve, and d’ (d prime). These measures may be defined as

<table>
<thead>
<tr>
<th>Measure</th>
<th>Definition</th>
</tr>
</thead>
<tbody>
<tr>
<td>Sensitivity</td>
<td>VP/(VP+ FN)</td>
</tr>
<tr>
<td>Specificity</td>
<td>VN/(FP + VN)</td>
</tr>
<tr>
<td>Accuracy</td>
<td>VP + VN</td>
</tr>
<tr>
<td>VP*</td>
<td>VP/(VP + FP)</td>
</tr>
<tr>
<td>FP*</td>
<td>(FP/(VP + FP)</td>
</tr>
<tr>
<td>d’</td>
<td>z(VP*) - z(FP*)</td>
</tr>
<tr>
<td>d’</td>
<td>sqrt(2) * z(AUC)</td>
</tr>
<tr>
<td>beta</td>
<td>prob(X/S)/(prob(X/N)</td>
</tr>
</tbody>
</table>

Although only one point is found, we can form a graphical display of VP versus FP as a smooth curve as a function of the decision criterion. The smooth curve assumes normality whereas the other merely are the two line segments between the points (0,0), (FP,VP), (1,1). The resulting correlation between the inferred continuous state of the world and the dichotomous decision process is a biserial correlation.

When using table input, the values can be counts and thus greater than 1 or merely probabilities.
which should add up to 1. Base Rates and Selection Ratios are proportions and thus less than 1.

Value

\( \phi \) Phi coefficient of the two by two table
\( \text{tetra} \) Tetrachoric (latent) coefficient inferred from the two by two table
\( r.bis \) Biserial correlation of continuous state of world with decision
observed The observed input (as a check)
probabilities Observed values/ total number of observations
conditional prob/rowSums(prob)
Accuracy percentage of True Positives + True Negatives
Sensitivity \( VP/(VP + FN) \)
Specificity \( VN/(FP + VN) \)
d.prime difference of True Positives versus True Negatives
beta ratio of ordinates at the decision point

bassAuckward

The Bass-Ackward factoring algorithm discussed by Goldberg

Description

Goldberg (2006) described a hierarchical factor structure organization from the “top down”. The original idea was to do successive factor analyses from 1 to nf factors organized by factor score correlations from one level to the next. Waller (2007) discussed a simple way of doing this for components without finding the scores. Using the factor correlations (from Gorsuch) to organize factors hierarchically results may be organized at many different levels. The algorithm may be applied to principal components (pca) or to true factor analysis.

Usage

bassAckward(r, nfactors = 1, fm = "minres", rotate = "oblimin", scores = "tenBerge", adjust=TRUE, plot=TRUE,cut=.3, use = "pairwise", cor = "cor", weight = NULL, correct = 0.5,...)
bassAckward.diagram(x,digits=2,cut = .3,labels=NULL,marg=c(1.5,.5,1.0,.5), main="BassAckward",items=TRUE,sort=TRUE,lr=TRUE,curves=FALSE,organize=TRUE,...)

Arguments

r A correlation matrix or a data matrix suitable for factoring
nfactors Factors from 1 to nfactors will be extracted. If nfactors is a a vector, then just the number of factors specified in the vector will be extracted. (See examples).
fm Factor method. The default is 'minres' factoring. Although to be consistent with the original Goldberg article, we can also do principal components (fm ="pca").
rotate What type of rotation to apply. The default for factors is oblimin, for pca is varimax.
scores What factor scoring algorithm should be used. The default is "tenBerge", other possibilities include "regression", or "bartlett"
adjust If using any other scoring procedure that "tenBerge" should we adjust the correlations for the lack of factor score fit?
plot By default draw a bassAckward diagram
use How to treat missing data. Use="pairwise" finds pairwise complete correlations.
cor What kind of correlation to find. The default is Pearson.
weight Should cases be weighted? Default, no.
correct If finding tetrachoric or polychoric correlations, what correction should be applied to empty cells (defaults to .5)
x The object returned by bassAckward
digits Number of digits to display on each path
cut Values greater than the abs=cut will be displayed in a path diagram.
labels Labels may be taken from the output of the bassAckward function or can be specified as a list.
marg Margins are set to be slightly bigger than normal to allow for a cleaner diagram
main The main title for the figure
items: if TRUE, show the items associated with the factors
sort: if TRUE, sort the items by factor loadings
lr: Should the graphic be drawn left to right or top to bottom
curves: Should we show the correlations between factors at the same level
organize: Rename and sort the factors at two lowest levels for a more pleasing figure
...
Other graphic parameters (e.g., cex)

Details
This is essentially a wrapper to the \texttt{fa} and \texttt{pca} combined with the \texttt{faCor} functions. They are called repeatedly and then the weights from the resulting solutions are used to find the factor/component correlations.

Although the default is do all factor solutions from 1 to the nfactors, this can be simplified by specifying just some of the factor solutions. Thus, for the 135 items of the spi, it is more reasonable to ask for 3, 5, and 27 item solutions.

The function \texttt{bassAckward.diagram} may be called using the \texttt{diagram} function or may be called directly.

The output from \texttt{bassAckward.diagram} is the sorted factor structure suitable for using \texttt{fa.lookup}.

Although not particularly pretty, it is possible to do Schmid-Leiman rotations at each level. Specify the rotation as rotate="schmid".

Value
\begin{tabular}{ll}
Call & Echo the call \\
fm & Echo the factor method used \\
itemfa & A list of the factor loadings at each level \\
bass.ack & A list of the factor correlations at each level \\
summary & The factors at each level \\
sumnames & Summary of the factor names \\
labels & Factor labels including items for each level \\
r & The correlation matrix analyzed \\
Phi & The factor correlations at each level \\
fa & The factor analysis loadings at each level, now includes Phi values \\
\end{tabular}

Note
Goldberg calculated factor/component scores and then correlated these. Waller suggests just looking at the unrotated components and then examining the correlations when rotating different numbers of components. I do not follow the Waller procedure, but rather find successive factors and then find factor/component correlations following Gorsuch.

Bechtoldt

Seven data sets showing a bifactor solution.

Description

Holzinger-Swineford (1937) introduced the bifactor model of a general factor and uncorrelated group factors. The Holzinger data sets are original 14 * 14 matrix from their paper as well as a 9 *9 matrix used as an example by Joreskog. The Thurstone correlation matrix is a 9 * 9 matrix of correlations of ability items. The Reise data set is 16 * 16 correlation matrix of mental health items. The Bechtoldt data sets are both 17 x 17 correlation matrices of ability tests.

Usage

data(Thurstone)
data(Thurstone.33)
data(Thurstone.9)
data(Holzinger)
data(Holzinger.9)
data(Bechtoldt)
data(Bechtoldt.1)
data(Bechtoldt.2)
data(Reise)
Holzinger and Swineford (1937) introduced the bifactor model (one general factor and several group factors) for mental abilities. This is a nice demonstration data set of a hierarchical factor structure that can be analyzed using the \texttt{omega} function or using \texttt{sem}. The bifactor model is typically used in measures of cognitive ability.

There are several ways to analyze such data. One is to use the \texttt{omega} function to do a hierarchical factoring using the Schmid-Leiman transformation. This can then be done as an exploratory and then as a confirmatory model using \texttt{omegaSem}. Another way is to do a regular factor analysis and use either a \texttt{bifactor} or \texttt{biquartimin} rotation. These latter two functions implement the Jennrich and Bentler (2011) bifactor and biquartimin transformations. The \texttt{bifactor} rotation suffers from the problem of local minima (Mansolf and Reise, 2016) and thus a mixture of exploratory and confirmatory analysis might be preferred.

The 14 variables are ordered to reflect 3 spatial tests, 3 mental speed tests, 4 motor speed tests, and 4 verbal tests. The sample size is 355.

Another data set from Holzinger (Holzinger.9) represents 9 cognitive abilities (Holzinger, 1939) and is used as an example by Karl Joreskog (2003) for factor analysis by the MINRES algorithm and also appears in the LISREL manual as example NPV.KM.

Another classic data set is the 9 variable Thurstone problem which is discussed in detail by R. P. McDonald (1985, 1999) and is used as example in the sem package as well as in the PROC CALIS manual for SAS. These nine tests were grouped by Thurstone and Thurstone, 1941 (based on other data) into three factors: Verbal Comprehension, Word Fluency, and Reasoning. The original data came from Thurstone and Thurstone (1941) but were reanalyzed by Bechthold (1961) who broke the data set into two. McDonald, in turn, selected these nine variables from the larger set of 17 found in Bechtoldt.2. The sample size is 213.

Another set of 9 cognitive variables attributed to Thurstone (1933) is the data set of 4,175 students reported by Professor Brigham of Princeton to the College Entrance Examination Board. This set does not show a clear bifactor solution but is included as a demonstration of the differences between a maximum likelihood factor analysis solution versus a principal axis factor solution.

Tucker (1958) uses 9 variables from Thurstone and Thurstone (1941) for his example of interbattery factor analysis.

More recent applications of the bifactor model are to the measurement of psychological status. The Reise data set is a correlation matrix based upon >35,000 observations to the Consumer Assessment of Health Care Providers and Systems survey instrument. Reise, Morizot, and Hays (2007) describe a bifactor solution based upon 1,000 cases.

The five factors from Reise et al. reflect Getting care quickly (1-3), Doctor communicates well (4-7), Courteous and helpful staff (8,9), Getting needed care (10-13), and Health plan customer service (14-16).

The two Bechtoldt data sets are two samples from Thurstone and Thurstone (1941). They include 17 variables, 9 of which were used by McDonald to form the Thurstone data set. The sample sizes are 212 and 213 respectively. The six proposed factors reflect memory, verbal, words, space, number and reasoning with three markers for all except the rote memory factor. 9 variables from this set appear in the Thurstone data set.

Two more data sets with similar structures are found in the \texttt{Harman} data set. This includes the another 9 variables (with 696 subjects) from Holzinger used by Harman Link(\texttt{Harman.Holzinger}) as well as 8 affective variables from \texttt{link(burt)}.

Another data set that is worth examining for tests of bifactor structure is the holzinger.swineford data set which includes the original data from Holzinger and Swineford (1939) supplied by Keith Widaman. This is in psychTools.1.9.11 or later.
• Bechtoldt.1: 17 x 17 correlation matrix of ability tests, N = 212.
• Bechtoldt.2: 17 x 17 correlation matrix of ability tests, N = 213.
• Holzinger: 14 x 14 correlation matrix of ability tests, N = 355
• Holzinger.9: 9 x 9 correlation matrix of ability tests, N = 145
• Reise: 16 x 16 correlation matrix of health satisfaction items. N = 35,000
• Thurstone: 9 x 9 correlation matrix of ability tests, N = 213
• Thurstone.33: Another 9 x 9 correlation matrix of ability items, N=4175
• Thurstone.9: And yet another 9 x 9 correlation matrix of ability items, N =710

**bestScales**

*A bootstrap aggregation function for choosing most predictive unit weighted items*

**Description**

`bestScales` forms scales from the items/scales most correlated with a particular criterion and then cross validates on a hold out sample using unit weighted scales. This may be repeated `n.iter` times using either basic bootstrap aggregation (bagging) techniques or K-fold cross validation. Thus, the technique is known as **BISCUIT** (Best Items Scales that are Cross validated, Unit weighted, Informative, and Transparent). Given a dictionary of item content, `bestScales` will sort by criteria correlations and display the item content. Options for bagging (bootstrap aggregation) are included. An alternative to unit weighting is to weight items by their zero order correlations (cross validated) with the criteria. This weighted version is called **BISCWIT** and is an optional output.

**Usage**

```r
bestScales(x,criteria,min.item=NULL,max.item=NULL, delta = 0,
    cut=.1, n.item =10, wtd.cut=0, wtd.n=10,
    n.iter =1, folds=1, p.keyed=.9,
    overlap=FALSE, dictionary=NULL, check=TRUE, impute="none",log.p=FALSE,digits=2)
```

```r
bestItems(x,criteria=1,cut=.1, n.item=10,raw=TRUE, abs=TRUE,
    dictionary=NULL,check=FALSE,digits=2)
```

**Arguments**

- **x**: A data matrix or data frame depending upon the function.
- **criteria**: Which variables (by name or location) should be the empirical target for `bestScales` and `bestItems`. May be a separate object.
- **min.item**: Find unit weighted and correlation weighted scales from `min.item` to `max.item`
- **max.item**: These are all summarized in the `final.multi.valid` object
- **delta**: Return items where the predicted $r + \delta \cdot se$ of $r < \max$ value
- **cut**: Return all values in $\text{abs}(x[,c1]) > \text{cut}$.
- **wtd.cut**: When finding the weighted scales, use all items with zero order correlations > `wtd.cut`
- **wtd.n**: When finding the weighted scales, use the `wtd.n` items that are > than `wtd.cut`
- **raw**: Raw data (find the correlations) or a correlation matrix (raw=FALSE)
- **abs**: if TRUE, sort by absolute value in `bestItems`
- **dictionary**: a data.frame with rownames corresponding to rownames in the $f$loadings matrix or colnames of the data matrix or correlation matrix, and entries (may be multiple columns) of item content.
- **check**: if TRUE, delete items with no variance
- **n.item**: How many items make up an empirical scale, or (bestItems, show the best `n.items`)
- **overlap**: Are the correlations with other criteria fair game for `bestScales`
When finding the best scales, and thus the correlations with the criteria, how should we handle missing data? The default is to drop missing items. (That is to say, to use pairwise complete correlations.)

n.iter
How many times to perform a bootstrap estimate. Replicate the best item function n.iter times, sampling roughly 1-1/e of the cases each time, and validating on the remaining 1/e of the cases for each iteration.

folds
If folds > 1, this is k-folds validation. Note, set n.iter > 1 to do bootstrap aggregation, or set folds > 1 to do k-folds.

p.keyed
The proportion of replications needed to include items in the final best keys.

log.p
Select items based upon the log of the probability of the correlations. This will only have an effect if the number of pairwise cases differs drastically from pair to pair.

digits
round to digits when showing output.

Details

There are a number of procedures that can be used for predicting criteria from a set of predictors. The generic term for this is "machine learning" or "statistical learning". The basic logic of these procedures is to find a set of items that best predict a criteria according to some fit statistic and then cross validate these items numerous times. "lasso" regression (least absolute shrinkage and selection) is one such example. bestScales differs from these procedures by unit weighting items chosen from their zero order correlations with the criteria rather than weighting the partial correlations ala regression. This is an admittedly simple procedure that takes into account the well known finding (Wilks, 1938; Wainer, 1976; Dawes, 1979; Waller, 2008) that although regression weights are optimal for any particular data set, unit weights are almost as good (fungible) and more robust across sample variation.

Following some suggestions, we have added the ability to find scales where items are weighted by their zero order correlations with the criteria. This is effectively a compromise between unit weighting and regression weights (where the weights are the zero order correlations times the inverse of the correlation matrix). This weighted version may be thought of as BISCWIT in contrast to the unit weighted version BISCUIT.

To be comparable to other ML algorithms, we now consider multiple solutions (for number of items >= min.item to max.item). The final scale consists of the number items which maximize the validity or at least are within delta * standard error of r of the maximum.

Thus, bestScales will find up to n.items per criterion that have absolute correlations with a criterion greater than cut. If the overlap option is FALSE (default) the other criteria are not used. This is an example of “dust bowl empiricism” in that there is no latent construct being measured, just those items that most correlate with a set of criteria. The empirically identified items are then formed into scales (ignoring concepts of internal consistency) which are then correlated with the criteria.

Clearly, bestScales is capitalizing on chance associations. Thus, we should validate the empirical scales by deriving them on a fraction of the total number of subjects, and cross validating on the remaining subjects. (This is known both as K-fold cross validation and bagging. Both may be done). If folds > 1, then a k-fold cross validation is done. This removes 1/k (a fold) from the sample for the derivation sample and validates on that remaining fold. This is done k-folds times. Traditional cross validation would thus be a k-fold with k =2. More modern applications seem to prefer k =10 to have 90% derivation sample and a 10% cross validation sample.

The alternative, known as ‘bagging’ is to do a bootstrap sample (which because it is sampling with replacement will typically extract 1- 1/e = 63.2% of the sample) for the derivation sample (the bag) and then validate it on the remaining 1/e of the sample (the out of bag). This is done n.iter times. This should be repeated multiple times (n.iter > 1, e.g. n.iter=1000) to get stable cross validations.
One can compare the validity of these two approaches by trying each. The average predictability of the n.iter samples are shown as are the average validity of the cross validations. This can only be done if x is a data matrix/data.frame, not a correlation matrix. For very large data sets (e.g., those from SAPA) these scales seem very stable.

**bestScales** is effectively a straightforward application of ‘bagging’ (bootstrap aggregation) and machine learning as well as k-fold validation.

The criteria can be the colnames of elements of x, or can be a separate data.frame. **bestItems** and **lookup** are simple helper functions to summarize correlation matrices or factor loading matrices. **bestItems** will sort the specified column (criteria) of x on the basis of the (absolute) value of the column. The return as a default is just the rowname of the variable with those absolute values > cut. If there is a dictionary of item content and item names, then include the contents as a two column matrix with rownames corresponding to the item name and then as many fields as desired for item content. (See the example dictionary **bfi.dictionary**).

The derived model can be further validated against yet another hold out sample using the **predict.psych** function if given the best scale object and the new data set.

**Value**

**bestScales** returns the correlation of the empirically constructed scale with each criteria and the items used in the scale. If a dictionary is specified, it also returns a list (value) that shows the item content. Also returns the keys.list so that scales can be found using **cluster.cor** or **scoreItems**. If using replications (bagging or kfold) then it also returns the best.keys, a list suitable for scoring.

There are actually four keys lists reported.

best.keys are all the items used to form unit weighted scales with the restriction of n.item.

weights may be used in the **scoreWtd** function to find scales based upon the raw correlation weights.

If the min.item and max.item options are used, then two more sets of weights are provided.

optimal.keys are a subset of the best.keys, taking just those items that increase the cross validation values up to the delta * se of the maximum. This is a slightly more parsimonious set.

optimal.weights is analogous to optimal keys, but for supplies weights for just those items that are used to predict cross validation values up to delta * se of the maximum.

The best.keys object is a list of items (with keying information) that may be used in subsequent analyses. These “best.keys” are formed into scale scores for the “final.valid” object which reports how well the best.keys work on the entire sample. This is, of course, not cross validated. Further cross validation can be done using the **predict.psych** function.

**scores** Are the unit weighted scores from the original items

**best.keys** A key list of those items that were used in the unit weighting.

**wtd.scores** Are the zero-order correlation based scores.

**weights** the scoring weights used

**final.multi.valid** An object with the unit weighted and correlation weighted correlations from low.step to high.step

The print and summary output list a number of summary statistics for each criteria. This is given for the default case (number of items fixed) and then if requested, the optimal values chosen from min.item to max.item:

The default statistics:

**derivation mean** Mean correlation of fixed length scale with the criteria, derivation sample
**bestScales**

- **derivation.sd** The standard deviation of these estimates
- **validation.m** The mean cross validated correlations with the criteria
- **validation.sd** The standard deviations of these estimates
- **final.valid** The correlation of the pooled models with all the subjects
- **final.wtd** The correlation of the pooled weighted model with all subjects
- **N.wtd** Number of items used in the final weighted model

The optimal number of items statistics:

- **n** The mean number of items meeting the criteria
- **unit** The mean derivation predictive validity
- **n.wtd** the mean number of items used in the wtd scales
- **wtd** The mean derivation wtd correlation
- **valid.n** The mean number of items in the cross validation sample
- **valid.unit** The mean cross validated unit weighted correlations
- **valid.wtd.n** The mean number of items used in the cross validated correlated weighed scale
- **valid.wtd** The mean cross validated weighted correlation with criteria
- **n.final** The optimal number of items on the final cross validation sample
- **n.wtd.final** The optimal number of weighted items on the final cross validation.

**derivation.mean**

- **bestItems** returns a sorted list of factor loadings or correlations with the labels as provided in the dictionary.

The stats object can be used to create **error.dots** plots to show the mean estimate and the standard error of the estimates. See the examples.

**Note**

Although **bestScales** was designed to form the best unit weighted scales, for large data sets, there seems to be some additional information in weighting by the average zero-order correlation.

To create a dictionary, create an object with row names as the item numbers, and the columns as the item content. See the link(bfi.dictionary) as an example.

**Note**

Although empirical scale construction is appealing, it has the basic problem of capitalizing on chance. Thus, be careful of over interpreting the results unless working with large samples. Iteration and bootstrapping aggregation (bagging) gives information on the stability of the solutions.

bfi

25 Personality items representing 5 factors

Description

25 personality self report items taken from the International Personality Item Pool (ipip.ori.org) were included as part of the Synthetic Aperture Personality Assessment (SAPA) web based personality assessment project. The data from 2800 subjects are included here as a demonstration set
for scale construction, factor analysis, and Item Response Theory analysis. Three additional demographic variables (sex, education, and age) are also included. This data set is deprecated and users are encouraged to use `bfi`.

**Usage**

```r
data(bfi)
```

**Format**

A data frame with 2800 observations on the following 28 variables. (The q numbers are the SAPA item numbers).

| A1     | Am indifferent to the feelings of others. (q_146) |
| A2     | Inquire about others’ well-being. (q_1162)      |
| A3     | Know how to comfort others. (q_1206)            |
| A4     | Love children. (q_1364)                         |
| A5     | Make people feel at ease. (q_1419)              |
| C1     | Am exacting in my work. (q_124)                 |
| C2     | Continue until everything is perfect. (q_530)   |
| C3     | Do things according to a plan. (q_619)          |
| C4     | Do things in a half-way manner. (q_626)         |
| C5     | Waste my time. (q_1949)                         |
| E1     | Don’t talk a lot. (q_712)                       |
| E2     | Find it difficult to approach others. (q_901)   |
| E3     | Know how to captivate people. (q_1205)          |
| E4     | Make friends easily. (q_1410)                   |
| E5     | Take charge. (q_1768)                           |
| N1     | Get angry easily. (q_952)                       |
| N2     | Get irritated easily. (q_974)                   |
| N3     | Have frequent mood swings. (q_1099)             |
| N4     | Often feel blue. (q_1479)                       |
| N5     | Panic easily. (q_1505)                          |
| O1     | Am full of ideas. (q_128)                       |
| O2     | Avoid difficult reading material.(q_316)        |
| O3     | Carry the conversation to a higher level. (q_492) |
| O4     | Spend time reflecting on things. (q_1738)       |
| O5     | Will not probe deeply into a subject. (q_1964)  |

**gender**  
Males = 1, Females =2

**education**  
1 = HS, 2 = finished HS, 3 = some college, 4 = college graduate 5 = graduate degree

**age**  
age in years
Details

This data set is deprecated and users are encouraged to use bfi. It is kept here backward compatibility for one more release.

The first 25 items are organized by five putative factors: Agreeableness, Conscientiousness, Extraversion, Neuroticism, and Openness. The scoring key is created using make.keys, the scores are found using score.items.

These five factors are a useful example of using irt.fa to do Item Response Theory based latent factor analysis of the polychoric correlation matrix. The endorsement plots for each item, as well as the item information functions reveal that the items differ in their quality.

The item data were collected using a 6 point response scale: 1 Very Inaccurate 2 Moderately Inaccurate 3 Slightly Inaccurate 4 Slightly Accurate 5 Moderately Accurate 6 Very Accurate as part of the Synthetic Aperture Personality Assessment (SAPA https://sapa-project.org) project. To see an example of the data collection technique, visit https://SAPA-project.org or the International Cognitive Ability Resource at https://icar-project.org. The items given were sampled from the International Personality Item Pool of Lewis Goldberg using the sampling technique of SAPA. This is a sample data set taken from the much larger SAPA data bank.

Note

This data set is deprecated and users are encouraged to use bfi. It is kept here backward compatibility for one more release.

Source

The items are from the ipip (Goldberg, 1999). The data are from the SAPA project (Revelle, Wilt and Rosenthal, 2010), collected Spring, 2010 (https://sapa-project.org).

bi.bars  

**bi.bars**  

Draw pairs of bargraphs based on two groups

Description

When showing e.g., age or education distributions for two groups, it is convenient to plot them back to back. bi.bars will do so.

Usage

bi.bars(x, var=NULL, grp=NULL, horiz, color, label=NULL, zero=FALSE, xlab, ylab, ...)

Arguments

x  
The data frame or matrix from which we specify the data

var  
The variable to plot

grp  
a grouping variable.

horiz  
horizontal (default) or vertical bars

color  
colors for the two groups – defaults to blue and red

label  
If specified, labels for the dependent axis

zero  
If TRUE, subtract the minimum value to make the numbers range from 0 to max-min. This is useful if showing heights

xlab  
axis label if appropriate

ylab  
y axis label otherwise

...  
Further parameters to pass to the graphing program

Details

A trivial, if useful, function to draw back to back histograms/barplots. One for each group.

Value

da graphic

```
biplot.psych

Draw biplots of factor or component scores by factor or component loadings

Description
Extends the biplot function to the output of fa, fa.poly or principal. Will plot factor scores and factor loadings in the same graph. If the number of factors > 2, then all pairs of factors are plotted. Factor score histograms are plotted on the diagonal. The input is the resulting object from fa, principal, or \code{linkfa.poly with the scores=TRUE option. Points may be colored according to other criteria.

Usage
```
## S3 method for class 'psych'
biplot(x, labels=NULL,cex=c(.75,1),main="Biplot from fa",hist.col="cyan",xlim.s=c(-3,3),ylim.s=c(-3,3),xlim.f=c(-1,1),ylim.f=c(-1,1),maxpoints=100,adjust=1.2,col,pos, arrow.len = 0.1,pch=16,choose=NULL,cuts=1,cutl=.0,group=NULL,smoother=FALSE,vars=TRUE,...)
```

Arguments
```
x
labels
if NULL, draw the points with the plot character (pch) specified. To identify the data points, specify labels= 1:n where n is the number of observations, or labels =rownames(data) where data was the data set analyzed by the factor analysis.
cex
A vector of plot sizes of the data labels and of the factor labels
main
A main title for a two factor biplot
hist.col
If plotting more than two factors, the color of the histogram of the factor scores
xlim.s
x limits of the scores. Defaults to plus/minus three sigma
ylim.s
y limits of the scores. Defaults to plus/minus three sigma
xlim.f
x limits of the factor loadings. Defaults to plus/minus 1.0
ylim.f
y limits of the factor loadings. Defaults to plus/minus 1.0
```

<td>more options for graphics</td>
</tr>
</tbody>
</table>

**Details**

Uses the generic biplot function to take the output of a factor analysis `fa`, `fa.poly` or principal components analysis `principal` and plot the factor/component scores along with the factor/component loadings.

This is an extension of the generic biplot function to allow more control over plotting points in a two space and also to plot three or more factors (two at time).

This will work for objects produced by `fa`, `fa.poly` or `principal` if they applied to the original data matrix. If however, one has a correlation matrix based upon the output from `tetrachoric` or `polychoric`, and has done either `fa` or `principal` on the correlations, then obviously, we can not do a biplot. However, both of those functions produce a weights matrix, which, in combination with the original data can be used to find the scores by using `factor.scores`. Since biplot.psych is looking for two elements of the x object: x$loadings and x$scores, you can create the appropriate object to plot. See the third example.

`fa, fa.poly, principal, fa.plot, pairs.panels`
Examples

```r
# the standard example
data(USArrests)
fa2 <- fa(USArrests, 2, scores = TRUE)
biplot(fa2, labels = rownames(USArrests))

# plot the 3 factor solution
# data(bfi)
fa3 <- fa(psychTools::bfi[1:200, 1:15], 3, scores = TRUE)
biplot(fa3)
# just plot factors 1 and 3 from that solution
biplot(fa3, choose = c(1, 3))

# fa2 <- fa(psychTools::bfi[16:25], 2) # factor analysis
fa2$scores <- fa2$scores[1:100,] # just take the first 100
# now plot with different colors and shapes for males and females
biplot(fa2, pch = c(24, 21)[psychTools::bfi[1:100, "gender"],
                          group = psychTools::bfi[1:100, "gender"],
                          main = "Biplot of Conscientiousness and Neuroticism by gender")

r <- cor(psychTools::bfi[1:200, 1:10], use = "pairwise") # find the correlations
f2 <- fa(r, 2)
x <- list()
x$scores <- factor.scores(psychTools::bfi[1:200, 1:10], f2)
x$loadings <- f2$loadings
class(x) <- c('psych', 'fa')
biplot(x, main = "biplot from correlation matrix and factor scores")
```

---

**block.random**

Create a block randomized structure for n independent variables

**Description**

Random assignment of n subjects with an equal number in all of N conditions may done by block randomization, where the block size is the number of experimental conditions. The number of Independent Variables and the number of levels in each IV are specified as input. The output is a the block randomized design.

**Usage**

```r
block.random(n, ncond = NULL)
```

**Arguments**

- `n` The number of subjects to randomize. Must be a multiple of the number of experimental conditions
- `ncond` The number of conditions for each IV. Defaults to 2 levels for one IV. If more than one IV, specify as a vector. If names are provided, they are used, otherwise the IVs are labeled as IV1 ... IVn
bock

Value

blocks A matrix of subject numbers, block number, and randomized levels for each IV

Note

Prepared for a course on Research Methods in Psychology [https://personality-project.org/revelle/syllabi/205/205.syllabus.html](https://personality-project.org/revelle/syllabi/205/205.syllabus.html)

bock Bock and Liberman (1970) data set of 1000 observations of the LSAT

Description

An example data set used by McDonald (1999) as well as other discussions of Item Response Theory makes use of a data table on 10 items (two sets of 5) from the Law School Admissions Test (LSAT). Included in this data set is the original table as well as the responses for 1000 subjects on the first set (Figure Classification) and second set (Debate).

Usage

data(bock)

Format

A data frame with 32 observations on the following 8 variables.

index 32 response patterns
Q1 Responses to item 1
Q2 Responses to item 2
Q3 Responses to item 3
Q4 Responses to item 4
Q5 Responses to item 5
Ob6 count of observations for the section 6 test
Ob7 count of observations for the section 7 test

Two other data sets are derived from the bock dataset. These are converted using the `table2df` function.

lsat6 responses to 5 items for 1000 subjects on section 6
lsat7 responses to 5 items for 1000 subjects on section 7
Details

The lsat6 data set is analyzed in the ltm package as well as by McDonald (1999). lsat7 is another 1000 subjects on part 7 of the LSAT. Both sets are described by Bock and Lieberman (1970). Both sets are useful examples of testing out IRT procedures and showing the use of tetrachoric correlations and item factor analysis using the irt.fa function.

cattell  
12 cognitive variables from Cattell (1963)

Description

Rindskopf and Rose (1988) use this data set to demonstrate confirmatory second order factor models. It is a nice example data set to explore hierarchical structure and alternative factor solutions. It contains measures of fluid and crystallized intelligence.

Usage

data("cattell")

Format

A correlation matrix of the following 12 variables from 277 7th and 8th graders

Verbal  A verbal ability test from Thurstone
Verbal2  A verbal ability test from Thurstone
Space1  A Spatial ability test from Thurstone
Space2  A Spatial ability test from Thurstone
Reason1  A reasoning test from Thurstone
Reason2  A reasoning test from Thurstone
Number1  A Numerical ability test from Thurstone
Number2  A Numerical ability test from Thurstone
IPATSer  A "culture fair" series from the IPAT
IPATCLAS  A "culture fair" classification test from the IPAT
IPATMatr  A "culture fair" matrix reasoning test from the IPAT
IPATTop  A "culture fair" topology test from the IPAT
Details

Cattell (1963) reported on 8 cognitive variables from Thurstone and four from the Institute for Personality Assessment Test (IPAT). Rindskopf and Rose (1988) use this data set as an example of second order factor analysis. It is thus a nice set for examining alternative solutions such as bifactor rotation, omega hierarchical, as well as esem and interbattery factor analysis.

circ.tests Apply four tests of circumplex versus simple structure

Description

Rotations of factor analysis and principal components analysis solutions typically try to represent correlation matrices as simple structured. An alternative structure, appealing to some, is a circumplex structure where the variables are uniformly spaced on the perimeter of a circle in a two dimensional space. Generating these data is straightforward, and is useful for exploring alternative solutions to affect and personality structure.

Usage

circ.tests(loads, loading = TRUE, sorting = TRUE)

Arguments

loads A matrix of loadings loads here
loading Are these loadings or a correlation matrix loading
sorting Should the variables be sorted sorting
Details

“A common model for representing psychological data is simple structure (Thurstone, 1947). According to one common interpretation, data are simple structured when items or scales have non-zero factor loadings on one and only one factor (Revelle & Rocklin, 1979). Despite the commonplace application of simple structure, some psychological models are defined by a lack of simple structure. Circumplexes (Guttman, 1954) are one kind of model in which simple structure is lacking.

“A number of elementary requirements can be teased out of the idea of circumplex structure. First, circumplex structure implies minimally that variables are interrelated; random noise does not a circumplex make. Second, circumplex structure implies that the domain in question is optimally represented by two and only two dimensions. Third, circumplex structure implies that variables do not group or clump along the two axes, as in simple structure, but rather that there are always interstitial variables between any orthogonal pair of axes (Saucier, 1992). In the ideal case, this quality will be reflected in equal spacing of variables along the circumference of the circle (Gurtman, 1994; Wiggins, Steiger, & Gaelick, 1981). Fourth, circumplex structure implies that variables have a constant radius from the center of the circle, which implies that all variables have equal communality on the two circumplex dimensions (Fisher, 1997; Gurtman, 1994). Fifth, circumplex structure implies that all rotations are equally good representations of the domain (Conte & Plutchik, 1981; Larsen & Diener, 1992). (Acton and Revelle, 2004)

Acton and Revelle reviewed the effectiveness of 10 tests of circumplex structure and found that four did a particularly good job of discriminating circumplex structure from simple structure, or circumplexes from ellipsoidal structures. Unfortunately, their work was done in Pascal and is not easily available. Here we release R code to do the four most useful tests:

1 The Gap test of equal spacing
2 Fisher’s test of equality of axes
3 A test of indifference to Rotation
4 A test of equal Variance of squared factor loadings across arbitrary rotations.

To interpret the values of these various tests, it is useful to compare the particular solution to simulated solutions representing pure cases of circumplex and simple structure. See the example output from circ.simulation and compare these plots with the results of the circ.test.

Value

A list of four items is returned. These are the gap, fisher, rotation and variance test results.

gaps  gap.test
fisher  fisher.test
RT  rotation.test
VT  variance.test

Note

Of the 10 criterion discussed in Acton and Revelle (2004), these tests operationalize the four most useful.

circ.fa <- fa(circ.data,2) plot(circ.fa,title="Circumplex Structure") ct <- circ.tests(circ.fa) #compare with non-circumplex data simp.data <- item.sim(24,500) simp.fa <- fa(simp.data,2) plot(simp.fa,title="Simple Structure") st <- circ.tests(simp.fa) res <- rbind(ct[1:4],st[1:4]) rownames(res) <- c("circumplex","Simple") print(res,digits=2)

cluster.fit

cluster Fit: fit of the cluster model to a correlation matrix

Description

How well does the cluster model found by ICLUST fit the original correlation matrix? A similar algorithm factor.fit is found in VSS. This function is internal to ICLUST but has more general use as well.

In general, the cluster model is a Very Simple Structure model of complexity one. That is, every item is assumed to represent only one factor/cluster. Cluster fit is an analysis of how well this model reproduces a correlation matrix. Two measures of fit are given: cluster fit and factor fit. Cluster fit assumes that variables that define different clusters are orthogonal. Factor fit takes the loadings generated by a cluster model, finds the cluster loadings on all clusters, and measures the degree of fit of this somewhat more complicated model. Because the cluster loadings are similar to, but not identical to factor loadings, the factor fits found here and by factor.fit will be similar.

Usage

cluster.fit(original, load, clusters, diagonal = FALSE)

Arguments

original The original correlation matrix being fit load Cluster loadings – that is, the correlation of individual items with the clusters, corrected for item overlap clusters The cluster structure diagonal Should we fit the diagonal as well?
The cluster model is similar to the factor model: $R$ is fitted by $C'C$. Where $C$ <- Cluster definition matrix x the loading matrix. How well does this model approximate the original correlation matrix and how does this compare to a factor model?

The fit statistic is a comparison of the original (squared) correlations to the residual correlations. 
$$\text{Fit} = 1 - r^2/r^2$$ where $r^*$ is the residual correlation of data - model and model = $C'C$.

The cluster model is a reduced form of the factor loading matrix. That is, it is the product of the elements of the cluster matrix * the loading matrix.

How well does the complete loading matrix reproduce the correlation matrix?

fit
```

cluster.loadings

Find item by cluster correlations, corrected for overlap and reliability

Description

Given a n x n correlation matrix and a n x c matrix of -1,0,1 cluster weights for those n items on c clusters, find the correlation of each item with each cluster. If the item is part of the cluster, correct for item overlap. Part of the ICLUST set of functions, but useful for many item analysis problems.

Usage

```r
cluster.loadings(keys, r.mat, correct = TRUE, SMC=TRUE)
```
cluster.loadings

**Arguments**

<table>

</tr>
<tr>
<td>r.mat</td>
<td>A correlation matrix</td>
</tr>
<tr>
<td>correct</td>
<td>Correct for reliability</td>
</tr>
<tr>
<td>SMC</td>
<td>Use the squared multiple correlation as a communality estimate, otherwise use the greatest correlation for each variable</td>
</tr>
</tbody>
</table>

**Details**

Given a set of items to be scored as (perhaps overlapping) clusters and the intercorrelation matrix of the items, find the clusters and then the correlations of each item with each cluster. Correct for item overlap by replacing the item variance with its average within cluster inter-item correlation.

Although part of ICLUST, this may be used in any SAPA (https://sapa-project.org) application where we are interested in item-whole correlations of items and composite scales.

For information about SAPA see Revelle et al, 2010, 2016. For information about SAPA based measures of ability, see https://icar-project.org.

These loadings are particularly interpretable when sorted by absolute magnitude for each cluster (see ICLUST.sort).

cluster.loadings(clusters,r.mat)
```

---

**cluster.plot**  
*Plot factor/cluster loadings and assign items to clusters by their highest loading.*

**Description**

Cluster analysis and factor analysis are procedures for grouping items in terms of a smaller number of (latent) factors or (observed) clusters. Graphical presentations of clusters typically show tree structures, although they can be represented in terms of item by cluster correlations.

Cluster.plot plots items by their cluster loadings (taken, e.g., from ICLUST) or factor loadings (taken, e.g., from fa). Cluster membership may be assigned apriori or may be determined in terms of the highest (absolute) cluster loading for each item.

If the input is an object of class "kmeans", then the cluster centers are plotted.

**Usage**

```r
cluster.plot(ic.results, cluster = NULL, cut = 0, labels=NULL, title = "Cluster plot",pch=18,pos,show.points=TRUE,choose=NULL,...)
fa.plot(ic.results, cluster = NULL, cut = 0, labels=NULL,title,jiggle=FALSE,amount=.02,pch=18,pos,show.points=TRUE,choose=NULL,...)
factor.plot(ic.results, cluster = NULL, cut = 0, labels=NULL,title,jiggle=FALSE, amount=.02,pch=18,pos,show.points=TRUE,...) #deprecated
```

**Arguments**

- `ic.results`: A factor analysis or cluster analysis output including the loadings, or a matrix of item by cluster correlations. Or the output from a kmeans cluster analysis.
- `cluster`: A vector of cluster membership
- `cut`: Assign items to clusters if the absolute loadings are > cut
- `labels`: If row.names exist they will be added to the plot, or, if they don’t, labels can be specified. If labels =NULL, and there are no row names, then variables are labeled by row number.
- `title`: Any title
- `jiggle`: When plotting with factor loadings that are almost identical, it is sometimes useful to "jiggle" the points by jittering them. The default is to not jiggle.
cluster2keys

Convert a cluster vector (from e.g., kmeans) to a keys matrix suitable for scoring item clusters.

Description

The output of the kmeans clustering function produces a vector of cluster membership. The score.items and cluster.cor functions require a matrix of keys. cluster2keys does this.

May also be used to take the output of an ICLUST analysis and find a keys matrix. (By doing a call to the factor2cluster function.

Usage

cluster2keys(c)
Arguments

c
A vector of cluster assignments or an object of class “kmeans” that contains a vector of clusters.

Details

Note that because kmeans will not reverse score items, the clusters defined by kmeans will not necessarily match those of ICLUST with the same number of clusters extracted.

Value

keys
A matrix of keys suitable for score.items or cluster.cor

Author(s)

William Revelle

See Also

cluster.cor, score.items, factor2cluster, make.keys

Examples

test.data <- Harman74.cor$cov
kc <- kmeans(test.data,4)
keys <- cluster2keys(kc)
keys #these match those found by ICLUST
cluster.cor(keys,test.data)

---

cohen.d

Find Cohen d and confidence intervals

Description

Given a data.frame or matrix, find the standardized mean difference (Cohen’s d) and confidence intervals for each variable depending upon a grouping variable. Convert the d statistic to the r equivalent, report the student’s t statistic and associated p values, and return statistics for both values of the grouping variable. The Mahalanobis distance between the centroids of the two groups in the space defined by all the variables ia also found. Confidence intervals for Cohen d for one group (difference from 0) may also be found.

Usage

cohen.d(x, group, alpha=.05, std=TRUE, sort=NULL, dictionary=NULL, MD=TRUE)
d.robust(x, group, trim=.2)
cohen.d.ci(d, n=NULL, n2=NULL, n1=NULL, alpha=.05)
d.ci(d, n=NULL, n2=NULL, n1=NULL, alpha=.05)
cohen.d.by(x, group, group2, alpha=.05, MD=TRUE)
d2r(d)
r2d(rho)
d2t(d, n=NULL, n2=NULL, n1=NULL)
t2d(t, n=NULL, n2=NULL, n1=NULL)
m2t(m1, m2, s1, s2, n1=NULL, n2=NULL, n=NULL, pooled=TRUE)
**Arguments**

- **x**: A data frame or matrix
- **group**: Some dichotomous grouping variable
- **group2**: Apply cohen.d for each of the subgroups defined by group2
- **d**: An effect size
- **trim**: The amount of trimming used in finding the means and sds in d.robust
- **n**: Total sample size (of groups 1 and 2)
- **n1**: Sample size of group 1 (if only one group)
- **n2**: Sample size of group 2
- **pooled**: Pool the two variances
- **t**: Student’s t statistic
- **alpha**: 1-alpha is the width of the confidence interval
- **std**: Find the correlation rather covariance matrix
- **rho**: A correlation to be converted to an effect size
- **m1**: Mean of group 1
- **m2**: Mean of group 2
- **s1**: Standard deviation of group 1
- **s2**: Standard deviation of group 2
- **sort**: Should we sort (and if so, in which direction), the results of cohen.d? Directions are “decreasing” or “increasing”.
- **dictionary**: What are the items being described?
- **MD**: Find Mahalanobis distance in cohen.d.

**Details**

There are many ways of reporting how two groups differ. Cohen’s d statistic is just the differences of means expressed in terms of the pooled within group standard deviation. This is insensitive to sample size. \( r \) is the a universal measure of effect size that is a simple function of \( d \), but is bounded -1 to 1. The t statistic is merely \( d \times \sqrt{n}/2 \) and thus reflects sample size.

Confidence intervals for Cohen’s d may be found by converting the d to a t, finding the confidence intervals for t, and then converting those back to ds. This take advantage of the uniroot function and the non-centrality parameter of the t distribution.

The results of `cohen.d` may be displayed using the `error.dots` function. This will include the labels provided in the dictionary.

In the case of finding the confidence interval for a comparison against 0 (the one sample case), specify n1. This will yield a \( d = t/\sqrt{n1} \) whereas in the case of the difference between two samples, \( d = 2t/\sqrt{n} \) (for equal sample sizes \( n = n1 + n2 \)) or \( d = t/\sqrt{1/n1 + 1/n2} \) for the case of unequal sample sizes.

`cohen.d.by` will find Cohen’s d for groups for each subset of the data defined by group2. The summary of the output produces a simplified listing of the d values for each variable for each group.

`d.robust` follows Algina et al. 2005) to find trimmed means (trim =.2) and Winsorize variances (trim =.2). Supposedly, this provides a more robust estimate of effect sizes.

`m2t` reports Student’s t test for two groups given their means, standard deviations, and sample size. This is convenient when checking statistics where those estimates are provided, but the raw data are
not available. By default, it gives the pooled estimate of variance, but if pooled is FALSE, it applies Welch’s correction.

The Mahalanobis Distance combines the individual $d$s and weight them by their unique contribution: $D = \sqrt{d'R^{-1}d}$. By default, cohen.d will find the Mahalanobis distance between the two groups (if there is more than one DV.) This requires finding the correlation of all of the DVs and can fail if that matrix is not invertible because some pairs do not exist. Thus, setting MD=FALSE will prevent the Mahalanobis calculation.

**Value**

- **d**: Cohen’s $d$ statistic, including the upper and lower confidence levels
- **hedges.g**: Hedge’s $g$ statistic
- **M.dist**: Mahalanobis distance between the two groups
- **t**: Student’s $t$ statistic
- **r**: The point biserial $r$ equivalent of $d$
- **n**: sample size used for each analysis
- **p**: The probability of $|t|>0$
- **descriptive**: The descriptive statistics for each group

Description

Cohen’s kappa (Cohen, 1960) and weighted kappa (Cohen, 1968) may be used to find the agreement of two raters when using nominal scores. Light’s kappa is just the average cohen.kappa if using more than 2 raters.

weighted.kappa is (probability of observed matches - probability of expected matches)/(1 - probability of expected matches). Kappa just considers the matches on the main diagonal. Weighted kappa considers off diagonal elements as well.

Usage

cohen.kappa(x, w=NULL,n.obs=NULL,alpha=.05,levels=NULL)
wkappa(x, w = NULL)  #deprectated

Arguments

x Either a two by n data with categorical values from 1 to p or a p x p table. If a data array, a table will be found.
w A p x p matrix of weights. If not specified, they are set to be 0 (on the diagonal) and (distance from diagonal)^2.
n.obs Number of observations (if input is a square matrix.
alpha Probability level for confidence intervals
levels Specify the levels if some levels of x or y are completely missing. See Examples

Details

When categorical judgments are made with two categories, a measure of relationship is the phi coefficient. However, some categorical judgments are made using more than two outcomes. For example, two diagnosticians might be asked to categorize patients three ways (e.g., Personality disorder, Neurosis, Psychosis) or to categorize the stages of a disease. Just as base rates affect observed cell frequencies in a two by two table, they need to be considered in the n-way table (Cohen, 1960).

Kappa considers the matches on the main diagonal. A penalty function (weight) may be applied to the off diagonal matches. If the weights increase by the square of the distance from the diagonal, weighted kappa is similar to an Intra Class Correlation (ICC).

Derivations of weighted kappa are sometimes expressed in terms of similarities, and sometimes in terms of dissimilarities. In the latter case, the weights on the diagonal are 1 and the weights off the diagonal are less than one. In this case, if the weights are 1 - squared distance from the diagonal / k, then the result is similar to the ICC (for any positive k).

cohen.kappa may use either similarity weighting (diagonal = 0) or dissimilarity weighting (diagonal = 1) in order to match various published examples.

The input may be a two column data.frame or matrix with columns representing the two judges and rows the subjects being rated. Alternatively, the input may be a square n x n matrix of counts or proportion of matches. If proportions are used, it is necessary to specify the number of observations (n.obs) in order to correctly find the confidence intervals.
The confidence intervals are based upon the variance estimates discussed by Fleiss, Cohen, and Everitt who corrected the formulae of Cohen (1968) and Blashfield.

Some data sets will include data with numeric categories with some category values missing completely. In the sense that kappa is a measure of category relationship, this should not matter. But when finding weighted kappa, the number of categories weighted will be less than the number of categories potentially in the data. This can be remedied by specifying the levels parameter. This is a vector of the levels potentially in the data (even if some are missing). See the examples.

If there are more than 2 raters, then the average of all raters is known as Light’s kappa. (Conger, 1980).

Value

- **kappa**: Unweighted kappa
- **weighted.kappa**: The default weights are quadratic.
- **var.kappa**: Variance of kappa
- **var.weighted**: Variance of weighted kappa
- **n.obs**: number of observations
- **weight**: The weights used in the estimation of weighted kappa
- **confid**: The alpha/2 confidence intervals for unweighted and weighted kappa
- **plevel**: The alpha level used in determining the confidence limits

Note

As is true of many R functions, there are alternatives in other packages. The Kappa function in the vcd package estimates unweighted and weighted kappa and reports the variance of the estimate. The input is a square matrix. The ckappa and wkappa functions in the psy package take raw data matrices. The kappam.light function from the irr package finds Light’s average kappa.

To avoid confusion with Kappa (from vcd) or the kappa function from base, the function was originally named wkappa. With additional features modified from psy::ckappa to allow input with a different number of categories, the function has been renamed cohen.kappa.

Unfortunately, to make it more confusing, the weights described by Cohen are a function of the reciprocals of those discussed by Fleiss and Cohen. The cohen.kappa function uses the appropriate formula for Cohen or Fleiss-Cohen weights.

There are some cases where the large sample size approximation of Fleiss et al. will produce confidence intervals exceeding +/- 1. Clearly, for these cases, the upper (or lower for negative values) should be set to 1. Boot strap resampling shows the problem is that the values are not symmetric. See the last (unrun) example.

It is also possible to have more than 2 raters. In this case, cohen.kappa is reported for all pairs of raters (e.g. R1 and R2, R1 and R3, ... R3 and R4). To see the confidence intervals for these cohen.kappas, use the print command with the all=TRUE option. (See the example of multiple raters.)

**comorbidity**

Convert base rates of two diagnoses and their comorbidity into phi, Yule, and tetrachorics

---

**Description**

In medicine and clinical psychology, diagnoses tend to be categorical (someone is depressed or not, someone has an anxiety disorder or not). Cooccurrence of both of these symptoms is called comorbidity. Diagnostic categories vary in their degree of comorbidity with other diagnostic categories. From the point of view of correlation, comorbidity is just a name applied to one cell in a four fold table. It is thus possible to analyze comorbidity rates by considering the probability of the separate diagnoses and the probability of the joint diagnosis. This gives the two by two table needed for a phi, Yule, or tetrachoric correlation.

**Usage**

```r
comorbidity(d1, d2, com, labels = NULL)
```

**Arguments**

- `d1`: Proportion of diagnostic category 1
- `d2`: Proportion of diagnostic category 2
- `com`: Proportion of comorbidity (diagnostic category 1 and 2)
- `labels`: Names of categories 1 and 2

**Value**

- `twobytwo`: The two by two table implied by the input
- `phi`: Phi coefficient of the two by two table
- `Yule`: Yule coefficient of the two by two table
- `tetra`: Tetrachoric coefficient of the two by two table

**Author(s)**

William Revelle

comorbidity(.2,.15,.1,c("Anxiety","Depression"))
```
cor.plot Create an image plot for a correlation or factor matrix

Description

Correlation matrices may be shown graphically by using the image function to emphasize structure. This is a particularly useful tool for showing the structure of correlation matrices with a clear structure. Partially meant for the pedagogical value of the graphic for teaching or discussing factor analysis and other multivariate techniques.

Usage

```r
corPlot(r,numbers=TRUE,colors=TRUE,n=51,main=NULL,zlim=c(-1,1),
show.legend=TRUE, labels=NULL,n.legend=10,keep.par=TRUE,select=TRUE,pval=NULL,
cuts=c(.001,.01),scale=TRUE,cex,MAR,upper=TRUE,diag=TRUE,symmetric=TRUE,stars=FALSE,
adjust="holm",xaxis=1,ylas=2,gr=NULL,alpha=.75,min.length=NULL,...)
corPlotUpperLowerCi(R,numbers=TRUE,cuts=c(.001,.01,.05),select=NULL,
main="Upper and lower confidence intervals of correlations",adjust=FALSE,...)
cor.plot(r,numbers=TRUE,colors=TRUE,n=51,main=NULL,zlim=c(-1,1),
show.legend=TRUE, labels=NULL,n.legend=10,keep.par=TRUE,select=TRUE,pval=NULL,
cuts=c(.001,.01),scale=TRUE,cex,MAR,upper=TRUE,diag=TRUE,symmetric=TRUE,stars=FALSE,
adjust="holm",xaxis=1,ylas=0,ylas=2,gr=NULL,alpha=.75,min.length=NULL,...)
cor.plot.upperLowerCi(R,numbers=TRUE,cuts=c(.001,.01,.05),select=NULL,
main="Upper and lower confidence intervals of correlations",adjust=FALSE,...)
```

Arguments

- `r` A correlation matrix or the output of `fa`, `principal` or `omega`.
- `R` The object returned from `cor.ci`
- `numbers` Display the numeric value of the correlations. (As of September, 2019) Defaults to TRUE.
- `colors` Defaults to TRUE and colors use colors from the `colorRampPalette` from red through white to blue, but colors=FALSE will use a grey scale
- `n` The number of levels of shading to use. Defaults to 51
- `main` A title. Defaults to "correlation plot"
- `zlim` The range of values to color – defaults to -1 to 1. If specified as NULL, then defaults to min and max observed correlation.
- `show.legend` A legend (key) to the colors is shown on the right hand side
- `labels` if NULL, use column and row names, otherwise use labels
- `n.legend` How many categories should be labelled in the legend?
- `keep.par` restore the graphic parameters when exiting

When summarizing the correlations of large data bases or when teaching about factor analysis or cluster analysis, it is useful to graphically display the structure of correlation matrices. This is a simple graphical display using the image function.

The difference between mat.plot with a regular image plot is that the primary diagonal goes from the top left to the lower right. zlim defines how to treat the range of possible values. -1 to 1 and the color choice is more reasonable. Setting it as c(0,1) will lead to negative correlations treated as zero. This is advantageous when showing general factor structures, because it makes the 0 white. There is an interesting case when plotting correlations corrected for attenuation. Some of these might exceed 1. In this case, either set zlim = NULL (to use the observed maximum and minimum values) or all values above 1 will be given a slightly darker shade than 1, but do not differ.
The default shows a legend for the color coding on the right hand side of the figure.

Modified following suggestions by David Condon and Josh Wilt to use a more meaningful color choice ranging from dark red (-1) through white (0) to dark blue (1). Further modified to allow for color choices using the gr option (suggested by Lorien Elleman). Further modified to include the numerical value of the correlation. (Inspired by the corrplot package). These values may be scaled according the the probability values found in cor.ci or corr.test.

Unless specified, the font size is dynamically scaled to have a cex = 10/max(nrow(r),ncol(r). This can produce fairly small fonts for large problems. The font size of the labels may be adjusted using cex.axis which defaults to one.

By default cor.ci calls corPlotUpperLowerCi and scales the correlations based upon "significance" values. The correlations plotted are the upper and lower confidence boundaries. To show the correlations themselves, call corPlot directly.

If using the output of corr.test, the upper off diagonal will be scaled by the corrected probability, the lower off diagonal the scaling is the uncorrected probabilities.

If using the output of corr.test or cor.ci as input to corPlotUpperLowerCi, the upper off diagonal will be the upper bounds and the lower off diagonal the lower bounds of the confidence intervals. If adjust=TRUE, these will use the Holm or Bonferroni adjusted values (depending upon corr.test).

To compare the elements of two correlation matrices, corPlot the results from lowerUpper.

To do multiple corPlot on the same plot, specify that show.legend=FALSE and keep.par=FALSE. See the last examples.

Care should be taken when selecting rows and columns from a non-symmetric matrix (e.g., the corrected correlations from scoreItems or scoreOverlap).

To show a factor loading matrix (or any non-symmetric matrix), set symmetric=FALSE. Otherwise the correlations will be found.

---

cor.smooth

Smooth a non-positive definite correlation matrix to make it positive definite

---

Description

Factor analysis requires positive definite correlation matrices. Unfortunately, with pairwise deletion of missing data or if using tetrachoric or polychoric correlations, not all correlation matrices are positive definite. cor.smooth does a eigenvector (principal components) smoothing. Negative eigen values are replaced with 100 * eig.tol, the matrix is reproduced and forced to a correlation matrix using cov2cor.
Usage

cor.smooth(x,eig.tol=10^-12)
cor.smoother(x,cut=.01)

Arguments

x A correlation matrix or a raw data matrix.
eig.tol the minimum acceptable eigenvalue.
cut Report all abs(residuals) > cut

Details

The smoothing is done by eigen value decomposition. eigen values < eig.tol are changed to 100 * eig.tol. The positive eigen values are rescaled to sum to the number of items. The matrix is re-computed (eigen.vectors %*% diag(eigen.values) %*% t(eigen.vectors)) and forced to a correlation matrix using cov2cor. (See Bock, Gibbons and Muraki, 1988 and Wothke, 1993).

This does not implement the Knol and ten Berge (1989) solution, nor do nearcor and posdefify in sfsmisc, not does nearPD in Matrix. As Martin Maechler puts it in the posdefify function, "there are more sophisticated algorithms to solve this and related problems."

cor.smoother examines all of nvar minors of rank nvar-1 by systematically dropping one variable at a time and finding the eigen value decomposition. It reports those variables, which, when dropped, produce a positive definite matrix. It also reports the number of negative eigenvalues when each variable is dropped. Finally, it compares the original correlation matrix to the smoothed correlation matrix and reports those items with absolute deviations great than cut. These are all hints as to what might be wrong with a correlation matrix.

Value

The smoothed matrix with a warning reporting that smoothing was necessary (if smoothing was in fact necessary).

**cor.wt**

The sample size weighted correlation may be used in correlating aggregated data

Description

If using aggregated data, the correlation of the means does not reflect the sample size used for each mean. cor.wt in RCore does this and returns a covariance matrix or the correlation matrix. The cor.wt function weights by sample size or by standard errors and by default return correlations.

Usage

```
cor.wt(data,vars=NULL, w=NULL,sds=NULL, cor=TRUE)
```

Arguments

data A matrix or data frame
vars Variables to analyze
w A set of weights (e.g., the sample sizes)
cor.wt

sds Standard deviations of the samples (used if weighting by standard errors)
cor Report correlations (the default) or covariances

Details

A weighted correlation is just

\[ r_{ij} = \frac{\sum (wt_k(x_{ik} - x_{jk}))}{\sqrt{\sum wt_k \sum (x_{ik}^2 wt_k) \sum (x_{jk}^2)}} \]

where \( x_{ik} \) is a deviation from the weighted mean.

The weighted correlation is appropriate for correlating aggregated data, where individual data points might reflect the means of a number of observations. In this case, each point is weighted by its sample size (or alternatively, by the standard error). If the weights are all equal, the correlation is just a normal Pearson correlation.

Used when finding correlations of group means found using statsBy.

Value

cor The weighted correlation
xwt The data as weighted deviations from the weighted mean
wt The weights used (calculated from the sample sizes).
mean The weighted means
xc Unweighted, centered deviation scores from the weighted mean
xs Deviation scores weighted by the standard error of each sample mean

Note

A generalization of cov.wt in core R

Author(s)

William Revelle

See Also

See Also as cov.wt, statsBy

Examples

```r
means.by.age <- statsBy(sat.act,"age")
wt.cors <- cor.wt(means.by.age)
lowerMat(wt.cors$r) # show the weighted correlations
unwt <- lowerCor(means.by.age$mean)
mixed <- lowerUpper(unwt,wt.cors$r) # combine both results
cor.plot(mixed,TRUE,main="weighted versus unweighted correlations")
diff <- lowerUpper(unwt,wt.cors$r,TRUE)
cor.plot(diff,TRUE,main="differences of weighted versus unweighted correlations")
```
cor2dist

Convert correlations to distances (necessary to do multidimensional scaling of correlation data)

Description
A minor helper function to convert correlations (ranging from -1 to 1) to distances (ranging from 0 to 2). \( d = \sqrt{2(1 - r)} \).

Usage

cor2dist(x)

Arguments

- \( x \) If square, then assumed to be a correlation matrix, otherwise the correlations are found first.

Value
dist: a square matrix of distances.

Note
For an example of doing multidimensional scaling on data that are normally factored, see Revelle (in prep)

corCi

Bootstrapped and normal confidence intervals for raw and composite correlations

Description

Although normal theory provides confidence intervals for correlations, this is particularly problematic with Synthetic Aperture Personality Assessment (SAPA) data where the individual items are Massively Missing at Random. Bootstrapped confidence intervals are found for Pearson, Spearman, Kendall, tetrachoric, or polychoric correlations and for scales made from those correlations. If given a correlation matrix and sample size(s), normal theory confidence intervals are provided.
corCi(x, keys = NULL, n.iter = 100, p = 0.05, overlap = FALSE, poly = FALSE, method = "pearson", plot = TRUE, minlength = 5, n = NULL, ...)
cor.ci(x, keys = NULL, n.iter = 100, p = 0.05, overlap = FALSE, poly = FALSE, method = "pearson", plot = TRUE, minlength = 5, n = NULL, ...)

Arguments

x
The raw data, or a correlation matrix if not doing bootstrapping

keys
If NULL, then the confidence intervals of the raw correlations are found. Otherwise, composite scales are formed from the keys applied to the correlation matrix (in a logic similar to cluster.cor but without the bells and whistles) and the confidence of those composite scales intercorrelations.

n.iter
The number of iterations to bootstrap over. This will be very slow if using tetrachoric/or polychoric correlations.

p
The upper and lower confidence region will include 1-p of the distribution.

overlap
If true, the correlation between overlapping scales is corrected for item overlap.

poly
If FALSE, then find the correlations using the method specified (default to Pearson). If TRUE, the polychoric correlations will be found (slowly). Because the polychoric function uses multicores (if available), and corCi does as well, the number of cores used is options("mc.cores")^2.

method
"pearson", "spearman", "kendall"

plot
Show the correlation plot with correlations scaled by the probability values. To show the matrix in terms of the confidence intervals, use cor.plot.upperLowerCi.

minlength
What is the minlength to use in abbreviations of the cis? Defaults to 5

n
If finding confidence intervals from a correlation matrix, specify the n

...
Other parameters for axis (e.g., cex.axis to change the font size, srt to rotate the numbers in the plot)

Details

If given a correlation matrix, then confidence intervals are found based upon the sample sizes using the conventional r^2 z fisher transformation (fisherz and the normal distribution.

If given raw data, correlations are found. If keys are specified (the normal case), then composite scales based upon the correlations are found and reported. This is the same procedure as done using cluster.cor or scoreItems.

Then (with raw data) the data are recreated n.iter times by sampling subjects (rows) with replacement and the correlations (and composite scales) are found again (and again and again). Mean and standard deviations of these values are calculated based upon the Fisher Z transform of the correlations. Summary statistics include the original correlations and their confidence intervals. For those who want the complete set of replications, those are available as an object in the resulting output.

Although particularly useful for SAPA (https://sapa-project.org) type data where we have lots of missing data, this will work for any normal data set as well.

Although the correlations are shown automatically as a cor.plot, it is possible to show the upper and lower confidence intervals by using cor.plot.upperLowerCi. This will also return, invisibly, a matrix for printing with the lower and upper bounds of the correlations shown below and above the diagonal (see the first example).
**corCi**

**Value**
- **rho**  The original (composite) correlation matrix.
- **means**  Mean (of Fisher transformed) correlation retransformed back to the r units
- **sds**  Standard deviation of Fisher transformed correlations
- **ci**  Mean +/- alpha/2 of the z scores as well as the alpha/2 and 1-alpha/2 quantiles. These are labeled as lower.emp(irical), lower.norm(al), upper.norm, and upper.emp.
- **replicates**  The observed replication values so one can do one’s own estimates

**Author(s)**

William Revelle

**Examples**

```r
#find confidence intervals of a correlation matrix with specified sample size
ci <- corCi(Thurstone[1:6,1:6],n=213)
#show them
R <- cor.plot.upperLowerCi(ci) #show them graphically
R #show them as a matrix

#confidence intervals by bootstrapping requires raw data
corCi(psychTools::bfi[1:200,1:10]) # just the first 10 variables

#The keys have overlapping scales
keys <- list(agree=c("-A1","A2","A3","A4","A5"), conscientious=c("C1","C2","C3","-C4","-C5"), extraversion=c("-E1","-E2","E3","E4","E5"), neuroticism=c("N1","N2","N3","N4","N5"), openness=c("O1","-O2","O3","O4","-O5"), alpha=c("-A1","A2","A3","A4","A5","C1","C2","C3","-C4","-C5","N1","N2","N3","N4","N5"), beta = c("-E1","-E2","E3","E4","E5","O1","-O2","O3","O4","-O5"))

#do not correct for item overlap
rci <- corCi(psychoTools::bfi[1:200,],keys,n.iter=10,main="correlation with overlapping scales")
#also shows the graphic - note the overlap
#correct for overlap
rci <- cor.ci(psychoTools::bfi[1:200,],keys,overlap=TRUE, n.iter=10,main="Correct for overlap")
#show the confidence intervals
ci <- cor.plot.upperLowerCi(rci) #to show the upper and lower confidence intervals
ci #print the confidence intervals in matrix form
```
corFiml

Find a Full Information Maximum Likelihood (FIML) correlation or covariance matrix from a data matrix with missing data

Description

Makes use of functions adapted from the lavaan package to find FIML covariance/correlation matrices. FIML can be much slower than the normal pairwise deletion option of cor, but provides slightly more precise estimates.

Usage

corFiml(x, covar = FALSE, show = FALSE)

Arguments

x A data.frame or data matrix
covar By default, just return the correlation matrix. If covar is TRUE, return a list containing the covariance matrix and the ML fit function.
show If show=TRUE, then just show the patterns of missingness, but don’t do the FIML. Useful for understanding the process of fiml.

Details

In the presence of missing data, Full Information Maximum Likelihood (FIML) is an alternative to simply using the pairwise correlations. The implementation in the lavaan package for structural equation modeling has been adapted for the simpler case of just finding the correlations or covariances.

The pairwise solution for any pair of variables is insensitive to other variables included in the matrix. On the other hand, the ML solution depends upon the entire set of items being correlated. This will lead to slightly different solutions for different subsets of variables.

The basic FIML algorithm is to find the pairwise ML solution for covariances and means for every pattern of missingness and then to weight the solution by the size of every unique pattern of missingness.

Value

cor The correlation matrix found using FIML
cov The covariance matrix found using FIML
fx The ML fit function

Note

The functions used in lavaan are not exported and so have been copied (and simplified) to the psych package.

Author(s)

Wiliam Revelle
See Also

To use the resulting correlations, see `fa`. To see the pairwise pattern of missingness, see `count.pairwise`.

Examples

```r
rML <- corFiml(psychTools::bfi[20:27])
rpw <- cor(psychTools::bfi[20:27],use="pairwise")
round(rML - rpw,3)
mp <- corFiml(psychTools::bfi[20:27],show=TRUE)
mp
```

corr.test

Find the correlations, sample sizes, and probability values between elements of a matrix or data.frame.

Description

Although the `cor` function finds the correlations for a matrix, it does not report probability values. `cor.test` does, but for only one pair of variables at a time. `corr.test` uses `cor` to find the correlations for either complete or pairwise data and reports the sample sizes and probability values as well. For symmetric matrices, raw probabilities are reported below the diagonal and correlations adjusted for multiple comparisons above the diagonal. In the case of different x and ys, the default is to adjust the probabilities for multiple tests. Both `corr.test` and `corr.p` return raw and adjusted confidence intervals for each correlation.

Usage

```r
corr.test(x, y = NULL, use = "pairwise", method = "pearson", adjust = "holm",
alpha = .05, ci = TRUE, minlength = 5)
corr.p(r, n, adjust = "holm", alpha = .05, minlength = 5, ci = TRUE)
```

Arguments

- `x`: A matrix or dataframe
- `y`: A second matrix or dataframe with the same number of rows as x
- `use`: use="pairwise" is the default value and will do pairwise deletion of cases. use="complete" will select just complete cases.
- `method`: method="pearson" is the default value. The alternatives to be passed to `cor` are "spearman" and "kendall"
- `adjust`: What adjustment for multiple tests should be used? ("holm", "hochberg", "holmel", "bonferroni", "BH", "BY", "Fdr", "none"). See `p.adjust` for details about why to use "holm" rather than "bonferroni".
- `alpha`: alpha level of confidence intervals
- `r`: A correlation matrix
- `n`: Number of observations if using `corr.p`. May be either a matrix (as returned from `corr.test`) or a scaler. Set to n - np if finding the significance of partial correlations. (See below).
ci

By default, confidence intervals are found. However, this leads to a noticeable slowdown of speed, particularly for large problems. So, for just the rs, ts and ps, set ci=FALSE

minlength

What is the minimum length for abbreviations. Defaults to 5.

Details
corr.test uses the cor function to find the correlations, and then applies a t-test to the individual correlations using the formula

\[ t = \frac{r \sqrt{(n - 2)}}{\sqrt{1 - r^2}} \]

\[ se = \sqrt{\frac{1 - r^2}{n - 2}} \]

The t and Standard Errors are returned as objects in the result, but are not normally displayed. Confidence intervals are found and printed if using the print(short=FALSE) option. These are found by using the fisher z transform of the correlation and then taking the range \( r +/ - qnorm(\alpha/2) * se \) and the standard error of the z transforms is

\[ se = \sqrt{\frac{1}{n - 3}} \]

These values are then back transformed to be in correlation units. They are returned in the ci object.

The probability values may be adjusted using the Holm (or other) correction. If the matrix is symmetric (no y data), then the original p values are reported below the diagonal and the adjusted above the diagonal. Otherwise, all probabilities are adjusted (unless adjust="none"). This is made explicit in the output. Confidence intervals are shown for raw and adjusted probabilities in the ci object.

corr.p may be applied to the results of partial.r if n is set to n - s (where s is the number of variables partialed out) Fisher, 1924.

Value

- \( r \) The matrix of correlations
- \( n \) Number of cases per correlation
- \( t \) value of t-test for each correlation
- \( p \) two tailed probability of t for each correlation. For symmetric matrices, p values adjusted for multiple tests are reported above the diagonal.
- \( se \) standard error of the correlation
- \( ci \) the alpha/2 lower and upper values, as well as the (Holm or Bonferroni) adjusted confidence intervals.

Note

For very large matrices (> 200 x 200), there is a noticeable speed improvement if confidence intervals are not found.
correct.cor

See Also
cor.test for tests of a single correlation, Hmisc::rcorr for an equivalent function, r.test to test the difference between correlations, and cor.test.mat to test for equality of two correlation matrices. Also see cor.ci for bootstrapped confidence intervals of Pearson, Spearman, Kendall, tetrachoric or polychoric correlations. In addition cor.ci will find bootstrapped estimates of composite scales based upon a set of correlations (ala cluster.cor).

In particular, see p.adjust for a discussion of p values associated with multiple tests.

Other useful functions related to finding and displaying correlations include lowerCor for finding the correlations and then displaying the lower off diagonal using the lowerMat function. lowerUpper to compare two correlation matrices.

Examples

c <- corr.test(attitude)  #find the correlations and give the probabilities
c #show the results
c1 <- corr.test(attitude[1:3], attitude[4:6]) #reports all values corrected for multiple tests

#corr.test(sat.act[1:3],sat.act[4:6],adjust="none")  #don't adjust the probabilities

#take correlations and show the probabilities as well as the confidence intervals
print(corr.p(c1$r,n=30),short=FALSE)

#don't adjust the probabilities
print(corr.test(sat.act[1:3],sat.act[4:6],adjust="none"),short=FALSE)

correct.cor(x, y)

Arguments

x  A raw correlation matrix
y  Vector of reliabilities

Details

Disattenuated correlations may be thought of as correlations between the latent variables measured by a set of observed variables. That is, what would the correlation be between two (unreliable) variables be if both variables were measured perfectly reliably.

This function is mainly used if importing correlations and reliabilities from somewhere else. If the raw data are available, use score.items, or cluster.loadings or cluster.cor.

Examples of the output of this function are seen in cluster.loadings and cluster.cor.
Value

Raw correlations below the diagonal, reliabilities on the diagonal, disattenuated above the diagonal.

# corrected <- cor2cov(xc,1/alpha)
# diag(corrected) <- 1
Bartlett’s test that a correlation matrix is an identity matrix

Description

Bartlett (1951) proposed that \(-\ln(\det(R)^*(N-1 - (2p+5)/6)\) was distributed as chi square if \(R\) were an identity matrix. A useful test that residuals correlations are all zero. Contrast to the Kaiser-Meyer-Olkin test.

Usage

cortest.bartlett(R, n = NULL, diag=TRUE)

Arguments

R  A correlation matrix. (If R is not square, correlations are found and a warning is issued.

n  Sample size (if not specified, 100 is assumed).

diag  Will replace the diagonal of the matrix with 1s to make it a correlation matrix.

Details

More useful for pedagogical purposes than actual applications. The Bartlett test is asymptotically chi square distributed.

Note that if applied to residuals from factor analysis (fa) or principal components analysis (principal) that the diagonal must be replaced with 1s. This is done automatically if diag=TRUE. (See examples.)

An Alternative way of testing whether a correlation matrix is factorable (i.e., the correlations differ from 0) is the Kaiser-Meyer-Olkin KMO test of factorial adequacy.

Value

chisq  Assymptotically chisquare

p.value  Of chi square

df  The degrees of freedom

cortest.bartlett(f3r,n=213,diag=TRUE) # correct (by default)
```

cortest.mat  

Chi square tests of whether a single matrix is an identity matrix, or a pair of matrices are equal.

Description

Steiger (1980) pointed out that the sum of the squared elements of a correlation matrix, or the Fisher z score equivalents, is distributed as chi square under the null hypothesis that the values are zero (i.e., elements of the identity matrix). This is particularly useful for examining whether correlations in a single matrix differ from zero or for comparing two matrices. Jennrich (1970) also examined tests of differences between matrices.

Usage

cortest.normal(R1, R2 = NULL, n1 = NULL, n2 = NULL, fisher = TRUE) # the steiger test
cortest(R1, R2 = NULL, n1 = NULL, n2 = NULL, fisher = TRUE, cor = TRUE) # same as cortest.normal
cortest.jennrich(R1, R2, n1 = NULL, n2 = NULL) # the jennrich test
cortest.mat(R1, R2 = NULL, n1 = NULL, n2 = NULL) # an alternative test

Arguments

- **R1**: A correlation matrix. (If R1 is not rectangular, and cor=TRUE, the correlations are found).
- **R2**: A correlation matrix. If R2 is not rectangular, and cor=TRUE, the correlations are found. If R2 is NULL, then the test is just whether R1 is an identity matrix.
- **n1**: Sample size of R1
- **n2**: Sample size of R2
- **fisher**: Fisher z transform the correlations?
- **cor**: By default, if the input matrices are not symmetric, they are converted to correlation matrices. That is, they are treated as if they were the raw data. If cor=FALSE, then the input matrices are taken to be correlation matrices.
Details

There are several ways to test if a matrix is the identity matrix. The most well known is the chi square test of Bartlett (1951) and Box (1949). A very straightforward test, discussed by Steiger (1980) is to find the sum of the squared correlations or the sum of the squared Fisher transformed correlations. Under the null hypothesis that all the correlations are equal, this sum is distributed as chi square. This is implemented in `cortest` and `cortest.normal`.

Yet another test, is the Jennrich(1970) test of the equality of two matrices. This compares the differences between two matrices to the averages of two matrices using a chi square test. This is implemented in `cortest.jennrich`.

Yet another option `cortest.mat` is to compare the two matrices using an approach analogous to that used in evaluating the adequacy of a factor model. In factor analysis, the maximum likelihood fit statistic is

\[
 f = \log(\text{trace}(FF' + U^2)^{-1}R) - \log(\text{det}(FF' + U^2)^{-1}R) - n\text{.items}.
\]

This in turn is converted to a chi square

\[
 \chi^2 = (n\text{.obs} - 1 - (2*p + 5)/6 - (2*\text{factors})/3)) \times f \text{ (see fa.)}
\]

That is, the model \((M = FF' + U^2)\) is compared to the original correlation matrix \((R)\) by a function of \(M^{-1}R\). By analogy, in the case of two matrices, A and B, `cortest.mat` finds the chi squares associated with \(A^{-1}B\) and \(AB^{-1}\). The sum of these two \(\chi^2\) will also be a \(\chi^2\) but with twice the degrees of freedom.

Value

- `chi2` The chi square statistic
- `df` Degrees of freedom for the Chi Square
- `prob` The probability of observing the Chi Square under the null hypothesis.

Note

Both the `cortest.jennrich` and `cortest.normal` are probably overly stringent. The ChiSquare values for pairs of random samples from the same population are larger than would be expected. This is a good test for rejecting the null of no differences.

cosinor

### Functions for analysis of circadian or diurnal data

**Description**

Circadian data are periodic with a phase of 24 hours. These functions find the best fitting phase angle (cosinor), the circular mean, circular correlation with circadian data, and the linear by circular correlation.

**Usage**

```r
cosinor(angle,x=NULL,code=NULL,data=NULL,hours=TRUE,period=24,
plot=FALSE,opti=FALSE,na.rm=TRUE)
cosinor.plot(angle,x=NULL,data = NULL, IDloc=NULL, ID=NULL,hours=TRUE, period=24,
na.rm=TRUE,ylim=NULL,ylab="observed",xlab="Time (double plotted)",
main="Cosine fit",add=FALSE,multi=FALSE,typ="1",...)
cosinor.period(angle,x=NULL,code=NULL,data=NULL,hours=TRUE,period=seq(23,26,1),
plot=FALSE,opti=FALSE,na.rm=TRUE)
circadian.phase(angle,x=NULL,code=NULL,data=NULL,hours=TRUE,period=24,
plot=FALSE,opti=FALSE,na.rm=TRUE)
circadian.mean(angle,data=NULL,hours=TRUE,na.rm=TRUE)
circadian.sd(angle,data=NULL,hours=TRUE,na.rm=TRUE)
circadian.stats(angle,data=NULL,hours=TRUE,na.rm=TRUE)
circadian.F(angle,group,data=NULL,hours=TRUE,na.rm=TRUE)
circadian.reliability(angle,x=NULL,code=NULL,data = NULL,min=16,
oddeven=FALSE, hours=TRUE,period=24,plot=FALSE,opti=FALSE,na.rm=TRUE)
circular.mean(angle,na.rm=TRUE) #angles in radians
circadian.cor(angle,data=NULL,hours=TRUE,na.rm=TRUE) #angles in radians
circular.cor(angle,na.rm=TRUE) #angles in radians
circadian.linear.cor(angle,x=NULL,data=NULL,hours=TRUE)
```

**Arguments**

- `angle`: A data frame or matrix of observed values with the time of day as the first value (unless specified in code) angle can be specified either as hours or as radians.
- `code`: A subject identification variable.
- `data`: A matrix or data frame of data. If specified, then angle and code are variable names (or locations). See examples.
- `group`: If doing comparisons by groups, specify the group code.
The minimum number of observations per subject to use when finding split half reliabilities.

Reliabilities are based upon odd and even items (TRUE) or first vs. last half (FALSE). Default is first and last half.

Although time of day is assumed to have a 24 hour rhythm, other rhythms may be fit. If calling cosinor.period, a range may be specified.

Which column number is the ID field

What specific subject number should be plotted for one variable

if TRUE, then plot the first variable (angle)

opti=TRUE: iterative optimization (slow) or opti=FALSE: linear fitting (fast)

If TRUE, measures are in 24 hours to the day, otherwise, radians

A set of external variables to correlate with the phase angles

Should missing data be removed?

Specify the range of the y axis if the defaults don’t work

The label of the y axis

Labels for the x axis

the title of the graphic

If doing multiple (spaghetti) plots, set add = TRUE for the second and beyond plots

If doing multiple (spaghetti) plots, set multi=TRUE for the first and subsequent plots

Pass the line type to graphics

any other graphic parameters to pass

Details

When data represent angles (such as the hours of peak alertness or peak tension during the day), we need to apply circular statistics rather than the more normal linear statistics (see Jammalamadaka (2006) for a very clear set of examples of circular statistics). The generalization of the mean to circular data is to convert each angle into a vector, average the x and y coordinates, and convert the result back to an angle. A statistic that represents the compactness of the observations is R which is the (normalized) vector length found by adding all of the observations together. This will achieve a maximum value (1) when all the phase angles are the same and a minimum (0) if the phase angles are distributed uniformly around the clock.

The generalization of Pearson correlation to circular statistics is straightforward and is implemented in cor.circular in the circular package and in circadian.cor here. Just as the Pearson r is a ratio of covariance to the square root of the product of two variances, so is the circular correlation. The circular covariance of two circular vectors is defined as the average product of the sines of the deviations from the circular mean. The variance is thus the average squared sine of the angular deviations from the circular mean. Circular statistics are used for data that vary over a period (e.g., one day) or over directions (e.g., wind direction or bird flight). Jammalamadaka and Lund (2006) give a very good example of the use of circular statistics in calculating wind speed and direction.

The code from CircStats and circular was adapted to allow for analysis of data from various studies of mood over the day. Those two packages do not seem to handle missing data, nor do they take matrix input, but rather emphasize single vectors.

The cosinor function will either iteratively fit cosines of the angle to the observed data (opti=TRUE) or use the circular by linear regression to estimate the best fitting phase angle. If cos.t <- cos(time)
and \( \sin t = \sin(\text{time}) \) (expressed in hours), then \( \beta.c \) and \( \beta.s \) may be found by regression and the phase is
\[
sign(\beta.c) \ast \cos(\beta.c/\sqrt{\beta.c^2 + \beta.s^2}) \ast 12/\pi
\]

Simulations (see examples) suggest that with incomplete times, perhaps the optimization procedure yields slightly better fits with the correct phase than does the linear model, but the differences are very small. In the presence of noisy data, these advantages seem to reverse. The recommendation thus seems to be to use the linear model approach (the default). The fit statistic reported for cosinor is the correlation of the data with the model \[ \cos(\text{time} - \text{acrophase}) \].

The \textit{circadian.reliability} function splits the data for each subject into a first and second half (by default, or into odd and even items) and then finds the best fitting phase for each half. These are then correlated (using \textit{circadian.cor}) and this correlation is then adjusted for test length using the conventional Spearman-Brown formula. Returned as object in the output are the statistics for the first and second part, as well as an ANOVA to compare the two halves.

\texttt{circular.mean} and \texttt{circular.cor} are just \texttt{circadian.mean} and \texttt{circadian.cor} but with input given in radians rather than hours.

The \texttt{circadian.linear.cor} function will correlate a set of circular variables with a set of linear variables. The first (angle) variables are circular, the second (x) set of variables are linear.

The \texttt{circadian.F} will compare 2 or more groups in terms of their mean position. This is adapted from the equivalent function in the circular package. This is clearly a more powerful test the more each group is compact around its mean (large values of R).

**Value**

- \texttt{phase} The phase angle that best fits the data (expressed in hours if \texttt{hours=TRUE}).
- \texttt{fit} Value of the correlation of the fit. This is just the correlation of the data with the phase adjusted cosine.
- \texttt{mean.angle} A vector of mean angles
- \texttt{n,mean,sd} The appropriate circular statistic.
- \texttt{correl} A matrix of circular correlations or linear by circular correlations
- \texttt{R} \( R \) is the vector length (0-1) of the mean vector when finding circadian statistics using \texttt{circadian.stats}
- \texttt{z,p} \( z \) is the number of observations \( x R^2 \). \( p \) is the probability of a \( z \).
- \texttt{phase.rel} The reliability of the phase measures. This is the circular correlation between the two halves adjusted using the Spearman-Brown correction.
- \texttt{fit.rel} The split half reliability of the fit statistic.
- \texttt{split.F} Do the two halves differ from each other? One would hope not.
- \texttt{group1,group2} The statistics from each half
- \texttt{splits} The individual data from each half.

**Note**

These functions have been adapted from the circular package to allow for ease of use with circadian data, particularly for data sets with missing data and multiple variables of interest.

##

toa

Simulate the C(ues) T(endency) A(ction) model of motivation

Description

Dynamic motivational models such as the Dynamics of Action (Atkinson and Birch, 1970, Revelle, 1986) may be reparameterized as a simple pair of differential (matrix) equations (Revelle, 1986, 2008). This function simulates the dynamic aspects of the CTA. The CTA model is discussed in detail in Revelle and Condon (2015).

Usage

toa (n=3,t=5000, cues = NULL, act=NULL, inhibit=NULL,expect = NULL, consume = NULL, tendency = NULL, tstrength=NULL, type="both", fast=2,compare=FALSE,learn=TRUE,reward=NULL)
toa.15(n = 3, t = 5000, cues = NULL, act = NULL, inhibit = NULL, consume = NULL, ten = NULL, type = "both", fast = 2)

Arguments

- **n**: number of actions to simulate
- **t**: length of time to simulate
- **cues**: a vector of cue strengths
Details

A very thorough discussion of the CTA model is available from Revelle (2008). An application of the model is discussed in Revelle and Condon (2015). *cta.15* is the version used to produce the figures and analysis in Revelle and Condon (2015). *cta* is the most recent version and includes a learning function developed in collaboration with Luke Smillie at the University of Melbourne.

The dynamics of action (Atkinson and Birch, 1970) was a model of how instigating forces elicited action tendencies which in turn elicited actions. The basic concept was that action tendencies had inertia. That is, a wish (action tendency) would persist until satisfied and would not change without an instigating force. The consummatory strength of doing an action was thought in turn to reduce the action tendency. Forces could either be instigating or inhibitory (leading to "negaction").

Perhaps the simplest example is the action tendency (T) to eat a pizza. The instigating forces (F) to eat the pizza include the smell and look of the pizza, and once eating it, the flavor and texture. However, if eating the pizza, there is also a consummatory force (C) which was thought to reflect both the strength (gusto) of eating the pizza as well as some constant consummatory value of the activity (c). If not eating the pizza, but in a pizza parlor, the smells and visual cues combine to increase the tendency to eat the pizza. Once eating it, however, the consummatory effect is no longer zero, and the change in action tendency will be a function of both the instigating forces and the consummatory forces. These will achieve a balance when instigating forces are equal to the consummatory forces. The asymptotic strength of eating the pizza reflects this balance and does not require a "set point" or "comparator".

To avoid the problems of instigating and consummatory lags and the need for a decision mechanism, it is possible to reparameterize the original DOA model in terms of action tendencies and actions (Revelle, 1986). Rather than specifying inertia for action tendencies and a choice rule of always expressing the dominant action tendency, it is useful to distinguish between action tendencies (t) and the actions (a) themselves and to have actions as well as tendencies having inertial properties. By separating tendencies from actions, and giving them both inertial properties, we avoid the necessity of a lag parameter, and by making the decision rule one of mutual inhibition, the process is perhaps easier to understand. In an environment which affords cues for action (c), cues enhance action tendencies (t) which in turn strengthen actions (a). This leads to two differential equations, one describing the growth and decay of action tendencies (t), the other of the actions themselves (a).

\[ dt = Sc - Ca \]
and
\[ \text{da} = \text{Et} - \text{Ia} \]

(See Revelle and Condon (2015) for an extensive discussion of this model.)

\text{cta} simulates this model, with the addition of a learning parameter such that activities strengthen the connection between cues and tendencies. The learning part of the cta model is still under development. \text{cta.15} represents the state of the cta model as described in the Revelle and Condon (2015) article.

**Value**

- graphical output unless type="none"

- cues: echo back the cue input
- inhibition: echo back the inhibitory matrix
- time: time spent in each activity
- frequency: Frequency of each activity
- tendencies: average tendency strengths
- actions: average action strength

#not run
#cta() #default values, running over time
#cta(type="state") #default values, in a state space of tendency 1 versus tendency 2
#these next are examples without graphic output
#not run
#two introverts
#c2i <- c(.95,1.05)
#cta(n=2,t=10000,cues=c2i,type="none")
#two extraverts
#c2e <- c(3.95,4.05)
#cta(n=2,t=10000,cues=c2e,type="none")
#three introverts
#c3i <- c(.95,1,1.05)
#cta(3,t=10000,cues=c3i,type="none")
```
DensityBy

Create a 'violin plot' or density plot of the distribution of a set of variables

Description

Among the many ways to describe a data set, one is density plot for each value of a grouping variable and another is violin plot of multiple variables. A density plot shows the density for different groups to show effect sizes. A violin plot is similar to a box plot but shows the actual distribution. Median and 25th and 75th percentile lines are added to the display. If a grouping variable is specified, violinBy will draw violin plots for each variable and for each group.

Usage

violinBy(x, var=NULL, grp=NULL, grp.name=NULL, ylab="Observed", xlab="", main="Density plot", alpha=1, adjust=1, restrict=TRUE, xlim=NULL, add=FALSE, col=NULL, pch=20, scale=NULL, ...)  
densityBy(x, var=NULL, grp=NULL, freq=FALSE, col=c("blue","red","black"), alpha=.5, adjust=1, xlab="Variable", ylab="Density", main="Density Plot")

Arguments

x  A matrix or data.frame
var  The variable(s) to display
grp  A grouping variable
grp.name  If the grouping variable is specified, then what names should be give to the group?Defaults to 1:ngrp
ylab  The y label
xlab  The x label
main  Figure title
alpha  A degree of transparency (0=transparent ... 1 not transparent)
adjust  Allows smoothing of density histograms when plotting variables like height
freq  if TRUE, then plot frequencies (n * density)
restrict  Restrict the density to the observed max and min of the data
xlim  if not specified, will be .5 beyond the number of variables
add  Allows overplotting
col  Allows for specification of colours. The default for 2 groups is blue and red, for more group levels, rainbows.
pch  The plot character for the mean is by default a small filled circle. To not show the mean, use pch=NA
describe

scale
If NULL, scale the widths by the square root of sample size, otherwise scale by
the value supplied.

... Other graphic parameters

Details
Describe the data using a violin plot. Change alpha to modify the shading. The grp variable may be
used to draw separate violin plots for each of multiple groups.

Value
The density (y axis) by value (x axis) of the data (for densityBy) or a violin plot for each variable
(perhaps broken down by groups)

Note
Nothing yet

describe Basic descriptive statistics useful for psychometrics

Description
There are many summary statistics available in R; this function provides the ones most useful for
scale construction and item analysis in classic psychometrics. Range is most useful for the first pass
in a data set, to check for coding errors.

Usage
describe(x, na.rm = TRUE, interp=FALSE, skew = TRUE, ranges = TRUE, trim=.1,
type=3, check=TRUE, fast=NULL, quant=NULL, IQR=FALSE, omit=FALSE)
describeData(x, head=4, tail=4)
describeFast(x)
describe 83

Arguments

x          A data frame or matrix
na.rm      The default is to delete missing data. na.rm=FALSE will delete the case.
interp     Should the median be standard or interpolated
skew       Should the skew and kurtosis be calculated?
ranges     Should the range be calculated?
trim       trim=.1 – trim means by dropping the top and bottom trim fraction
type       Which estimate of skew and kurtosis should be used? (See details.)
check      Should we check for non-numeric variables? Slower but helpful.
fast       if TRUE, will do n, means, sds, min, max, ranges for an improvement in speed.
            If NULL, will switch to fast mode for large (ncol * nrow > 10^7) problems,
            otherwise defaults to fast = FALSE
quant      if not NULL, will find the specified quantiles (e.g. quant=c(.25,.75) will find the
            25th and 75th percentiles)
IQR        If TRUE, show the interquartile range
omit       Do not convert non-numeric variables to numeric, omit them instead
head       show the first 1:head cases for each variable in describeData
tail       Show the last nobs-tail cases for each variable in describeData

Details

In basic data analysis it is vital to get basic descriptive statistics. Procedures such as summary
and hmisc::describe do so. The describe function in the psych package is meant to produce the
most frequently requested stats in psychometric and psychology studies, and to produce them in
an easy to read data.frame. The results from describe can be used in graphics functions (e.g.,
error.crosses).

The range statistics (min, max, range) are most useful for data checking to detect coding errors, and
should be found in early analyses of the data.

Although describe will work on data frames as well as matrices, it is important to realize that for
data frames, descriptive statistics will be reported only for those variables where this makes sense
(i.e., not for alphanumeric data).

If the check option is TRUE, variables that are categorical or logical are converted to numeric and
then described. These variables are marked with an * in the row name. This is somewhat slower.
Note that in the case of categories or factors, the numerical ordering is not necessarily the one
expected. For instance, if education is coded "high school", "some college", "finished college",
then the default coding will lead to these as values of 2, 3, 1. Thus, statistics for those variables
marked with * should be interpreted cautiously (if at all).

In a typical study, one might read the data in from the clipboard (read.clipboard), show the splom
plot of the correlations (pairs.panels), and then describe the data.

na.rm=FALSE is equivalent to describe(na.omit(x))

When finding the skew and the kurtosis, there are three different options available. These match the
choices available in skewness and kurtosis found in the e1071 package (see Joanes and Gill (1998)
for the advantages of each one).

If we define \( m_r = \frac{\sum (X - mx)^r}{n} \) then

Type 1 finds skewness and kurtosis by \( g_1 = m_3/(m_2)^{3/2} \) and \( g_2 = m_4/(m_2)^2 - 3 \).
Type 2 is \( G_1 = g_1 \sqrt{n} \frac{(n - 1)}{(n - 2)} \) and \( G_2 = (n - 1) \frac{[(n + 1)g_2 + 6]}{((n - 2)(n - 3))} \).

Type 3 is \( b_1 = \frac{((n - 1)/n)^{3/2} m_3}{m_3^{3/2}} \) and \( b_2 = \frac{((n - 1)/n)^{3/2} m_4}{m_2^2} \).

The additional helper function `describeData` just scans the data array and reports on whether the data are all numerical, logical/factorial, or categorical. This is a useful check to run if trying to get descriptive statistics on very large data sets where to improve the speed, the check option is FALSE.

An even faster overview of the data is `describeFast` which reports the number of total cases, number of complete cases, number of numeric variables and the number which are factors.

The fast=TRUE option will lead to a speed up of about 50% for larger problems by not finding all of the statistics (see NOTE).

To describe the data for different groups, see `describeBy`.

**Value**

A data.frame of the relevant statistics:

- item name
- item number
- number of valid cases
- mean
- standard deviation
- trimmed mean (with trim defaulting to .1)
- median (standard or interpolated)
- mad: median absolute deviation (from the median).
- minimum
- maximum
- skew
- kurtosis
- standard error

**Note**

For very large data sets that are data.frames, `describe` can be rather slow. Converting the data to a matrix first is recommended. However, if the data are of different types, (factors or logical), this is not possible. If the data set includes columns of character data, it is also not possible. Thus, a quick pass with `describeData` is recommended. Even faster is a quick pass with `describeFast` which just counts number of observations per variable and reports the type of data (numerical, factor, logical).

For the greatest speed, at the cost of losing information, do not ask for ranges or for skew and turn off check. This is done automatically if the fast option is TRUE or for large data sets.

Note that by default, fast=NULL. But if the number of cases x number of variables exceeds (ncol * nrow > 10^7), fast will be set to TRUE. This will provide just n, mean, sd, min, max, range, and standard errors. To get all of the statistics (but at a cost of greater time) set fast=FALSE.

The problem seems to be a memory limitation in that the time taken is an accelerating function of nvars * nob. Thus, for a largish problem (72,000 cases with 1680 variables) which might take 330 seconds, doing it as two sets of 840 variable cuts the time down to 80 seconds.

The object returned is a data frame with the normal precision of R. However, to control the number of digits displayed, you can set digits in a print command, rather than losing precision at the descriptive stats level. See the last two examples. One just sets the number of digits, one gives uses `signif` to make 'prettier' output where all numbers are displayed to the same number of digits.
The MAD (median absolute deviation from the median) is calculated using the mad function from the stats package in Core-R. Note that by default, the MAD is adjusted by a scaling factor (1.4826) that will give the expectation of the MAD to be the same as the standard deviation for normal data.

An interesting problem with describe is that a function with the same name is in the Hmisc package. Hmisc is loaded by qqgraph which in turn is loaded by SemPlot. So even if not directly loading HMisc, if you load SemPlot after loading psych, describe will not work, but the reverse order for loading should work.

print(des,digits=3) #show the output, but round to 3 (trailing) digits
print(des, signif=3) #round all numbers to the 3 significant digits
describeBy

Basic summary statistics by group

Description

Report basic summary statistics by a grouping variable. Useful if the grouping variable is some experi-
mental variable and data are to be aggregated for plotting. Partly a wrapper for by and describe

Usage

describeBy(x, group=NULL, mat=FALSE, type=3, digits=15,...)
describe.by(x, group=NULL, mat=FALSE, type=3,...)  # deprecated

Arguments

x a data.frame or matrix. See note for statsBy.
group a grouping variable or a list of grouping variables
mat provide a matrix output rather than a list
type Which type of skew and kurtosis should be found
digits When giving matrix output, how many digits should be reported?
... parameters to be passed to describe

Details

To get descriptive statistics for several different grouping variables, make sure that group is a list. In
the case of matrix output with multiple grouping variables, the grouping variable values are added
to the output.

The type parameter specifies which version of skew and kurtosis should be found. See describe
for more details.

An alternative function (statsBy) returns a list of means, n, and standard deviations for each group.
This is particularly useful if finding weighted correlations of group means using cor.wt. More
importantly, it does a proper within and between group decomposition of the correlation.

cohen.d will work for two groups. It converts the data into mean differences and pools the within
group standard deviations. Returns cohen.d statistic as well as the multivariate generalization (Ma-
halanobis D).

Value

A data.frame of the relevant statistics broken down by group:

item name
item number
number of valid cases
mean
standard deviation
median
mad: median absolute deviation (from the median)
minimum
maximum
**diagram**

skew
standard error

---

**Description**

Path models are used to describe structural equation models or cluster analytic output. These functions provide the primitives for drawing path models. Used as a substitute for some of the functionality of Rgraphviz.

**Usage**

diagram(fit,...)
dia.rect(x, y = NULL, labels = NULL, cex = 1, xlim = c(0, 1), ylim = c(0, 1), ...)
dia.ellipse(x, y = NULL, labels = NULL, cex=1,e.size=.05, xlim=c(0,1), ylim=c(0,1), ...)
dia.triangle(x, y = NULL, labels =NULL, cex = 1, xlim=c(0,1),ylim=c(0,1),...)
dia.ellipse1(x,y,e.size=.05,xlim=c(0,1),ylim=c(0,1),...)
dia.shape(x, y = NULL, labels = NULL, cex = 1,
e.size=.05, xlim=c(0,1), ylim=c(0,1), shape=1, ...)
dia.arrow(from,to,labels=NULL,scale=1,cex=1,adj=2,both=FALSE,pos=NULL,l.cex,gap.size,...)
dia.curve(from,to,labels=NULL,...)
dia.curved.arrow(from,to,labels=NULL,scale=1,both=FALSE,dir=NULL,...)
dia.self(location,labels=NULL,scale=.8,side=2,...)
dia.cone(x=0, y=-2, theta=45, arrow=TRUE,curves=TRUE,add=FALSE,labels=NULL,
xlim = c(-1, 1), ylim=c(-1,1),... )
Arguments

fit The results from a factor analysis fa, components analysis principal, omega reliability analysis, omega, cluster analysis iclust, topdown (bassAckward) bassAckward or confirmatory factor analysis, cfa, or structural equation model, sem, using the lavaan package.

x x coordinate of a rectangle or ellipse

y y coordinate of a rectangle or ellipse

e.size The size of the ellipse (scaled by the number of variables

labels Text to insert in rectangle, ellipse, or arrow

cex adjust the text size

l.cex Adjust the text size in arrows, defaults to cex which in turn defaults to 1

gap.size Tweak the gap in an arrow to be allow the label to be in a gap

adj Where to put the label along the arrows (values are then divided by 4)

both Should the arrows have arrow heads on both ends?
scale modifies size of rectangle and ellipse as well as the curvature of curves. (For curvature, positive numbers are concave down and to the left

from arrows and curves go from
to arrows and curves go to

location where is the rectangle?

shape Which shape to draw

xlim default ranges

ylim default ranges

side Which side of boxes should errors appear

theta Angle in degrees of vectors

arrow draw arrows for edges in dia.cone

add if TRUE, plot on previous plot

curves if TRUE, draw curves between arrows in dia.cone

pos The position of the text in . Follows the text positions of 1, 2, 3, 4 or NULL

dir Should the direction of the curve be calculated dynamically, or set as "up" or "left"

... Most graphic parameters may be passed here

Details

The diagram function calls fa.diagram, omega.diagram, ICLUST.diagram, lavaan.diagram or bassAckward.diagram depending upon the class of the fit input. See those functions for particular parameter values.

The remaining functions are the graphic primitives used by fa.diagram, structure.diagram, omega.diagram, ICLUST.diagram and het.diagram

They create rectangles, ellipses or triangles surrounding text, connect them to straight or curved arrows, and can draw an arrow from and to the same rectangle.

Each shape (ellipse, rectangle or triangle) has a left, right, top and bottom and center coordinate that may be used to connect the arrows.
Curves are double-headed arrows. By default they go from one location to another and curve either left or right (if going up or down) or up or down (going left to right). The direction of the curve may be set by dir="up" for left right curvature.

The helper functions were developed to get around the infelicities associated with trying to install Rgraphviz and graphviz.

These functions form the core of *fa.diagram, het.diagram*.

Better documentation will be added as these functions get improved. Currently the helper functions are just a work around for Rgraphviz.

dia.cone draws a cone with (optionally) arrows as sides and centers to show the problem of factor indeterminacy.

v9 <- sim.hierarchical()
f3 <- fa(v9, 3, rotate = "cluster")
fa.diagram(f3, error = TRUE, side = 3)
```

---

**draw.tetra**

*Draw a correlation ellipse and two normal curves to demonstrate tetrachoric correlation*

**Description**

A graphic of a correlation ellipse divided into 4 regions based upon x and y cutpoints on two normal distributions. This is also an example of using the layout function. Draw a bivariate density plot to show how tetrachorics work.

**Usage**

```r
draw.tetra(r, t1, t2, shade = TRUE)
draw.cor(r = .5, expand = 10, theta = 30, phi = 30, N = 101, nbcol = 30, box = TRUE,
        main = "Bivariate density  \( \rho = \) ", cuts = NULL, all = TRUE, ellipses = TRUE, ze = .15)
```

**Arguments**

- `r`: the underlying Pearson correlation defines the shape of the ellipse
- `t1`: X is cut at tau
- `t2`: Y is cut at Tau
- `shade`: shade the diagram (default is TRUE)
- `expand`: The relative height of the z axis
- `theta`: The angle to rotate the x-y plane
- `phi`: The angle above the plane to view the graph
- `N`: The grid resolution
- `nbcol`: The color resolution
- `box`: Draw the axes
- `main`: The main title
- `cuts`: Should the graphic show cuts (e.g., cuts = c(0, 0))
- `all`: Show all four parts of the tetrachoric
- `ellipses`: Draw a correlation ellipse
- `ze`: height of the ellipse if requested
**dummy.code**

*Create dummy coded variables*

**Description**

Given a variable `x` with `n` distinct values, create `n` new dummy coded variables coded 0/1 for presence (1) or absence (0) of each variable. A typical application would be to create dummy coded college majors from a vector of college majors. Can also combine categories by group. By default, NA values of `x` are returned as NA (added 10/20/17)

**Usage**

dummy.code(x, group=NULL, na.rm=TRUE, top=NULL, min=NULL)

**Arguments**

- **x**
  A vector to be transformed into dummy codes
- **group**
  A vector of categories to be coded as 1, all others coded as 0.
- **na.rm**
  If TRUE, return NA for all codes with NA in `x`
- **top**
  If specified, then just dummy code the top values, and make the rest NA
- **min**
  If specified, then dummy code all values >= min
Details

When coding demographic information, it is typical to create one variable with multiple categorical values (e.g., ethnicity, college major, occupation). `dummy.code` will convert these categories into n distinct dummy coded variables.

If there are many possible values (e.g., country in the SAPA data set) then specifying `top` will assign dummy codes to just a subset of the data.

If using dummy coded variables as predictors, remember to use n-1 variables.

If `group` is specified, then all values of `x` that are in group are given the value of 1, otherwise, 0. (Useful for combining a range of science majors into STEM or not. The example forms a dummy code of any smoking at all.)

Value

A matrix of dummy coded variables

Author(s)

William Revelle

Examples

```r
new <- dummy.code(sat.act$education)
new.sat <- data.frame(new,sat.act)
round(cor(new.sat,use="pairwise"),2)
#dum.smoke <- dummy.code(spi$smoke,group=2:9)
#table(dum.smoke,spi$smoke)
#dum.age <- dummy.code(round(spi$age/5)*5,top=5) #the most frequent five year blocks
```

Description

Dwyer (1937) introduced a technique for factor extension and used 8 cognitive variables from Thurstone. This is the example data set used in his paper.

Usage

data(Dwyer)

Format

The format is: num [1:8, 1:8] 1 0.58 -0.28 0.01 0.36 0.38 0.61 0.15 0.58 1 ... - attr(*, "dimnames")=List of 2 ..$ : chr [1:8] "V1" "V2" "V3" "V4" ...
..$ : chr [1:8] "V1" "V2" "V3" "V4" ...

Source

Data matrix retyped from the original publication.
**References**

Dwyer, Paul S. (1937), The determination of the factor loadings of a given test from the known factor loadings of other tests. Psychometrika, 3, 173-178

**Examples**

```
data(Dwyer)
Ro <- Dwyer[1:7,1:7]
Roe <- Dwyer[1:7,8]
fo <- fa(Ro,2,rotate="none")
fa.extension(Roe,fo)
```

---

**eigen.loadings**

Convert eigen vectors and eigen values to the more normal (for psychologists) component loadings

**Description**

The default procedures for principal component returns values not immediately equivalent to the loadings from a factor analysis. `eigen.loadings` translates them into the more typical metric of eigen vectors multiplied by the squareroot of the eigenvalues. This lets us find pseudo factor loadings if we have used princomp or eigen.

If we use `principal` to do our principal components analysis, then we do not need this routine.

**Usage**

```
eigen.loadings(x)
```

**Arguments**

- `x` the output from eigen or a list of class princomp derived from princomp

**Value**

A matrix of Principal Component loadings more typical for what is expected in psychometrics. That is, they are scaled by the square root of the eigenvalues.

**Note**

Useful for SAPA analyses

**Author(s)**

< revelle@northwestern.edu >
https://personality-project.org/revelle.html

**Examples**

```
x <- eigen(Harman74.cor$cov)
x$vectors[1:8,1:4] # as they appear from eigen
y <- princomp(covmat=Harman74.cor$cov)
y$loadings[1:8,1:4] # as they appear from princomp
eigen.loadings(x)[1:8,1:4] # rescaled by the eigen values
```
**ellipses**

**Plot data and 1 and 2 sigma correlation ellipses**

**Description**

For teaching correlation, it is useful to draw ellipses around the mean to reflect the correlation. This variation of the ellipse function from John Fox’s car package does so. Input may be either two vectors or a matrix or data.frame. In the latter cases, if the number of variables >2, then the ellipses are done in the *pairs.panels* function. Ellipses may be added to existing plots. The minkowski function is included as a generalized ellipse.

**Usage**

```r
effillses(x, y = NULL, add = FALSE, smooth=TRUE, lm=FALSE, data=TRUE, n = 2, span=2/3, iter=3, col = "red", xlab =NULL, ylab= NULL, size=c(1,2), ...) minkowski(r=2,add=FALSE,main=NULL,xl=1,yl=1)
```

**Arguments**

- **x**: a vector, matrix, or data.frame
- **y**: Optional second vector
- **add**: Should a new plot be created, or should it be added to?
- **smooth**: smooth = TRUE -> draw a loess fit
- **lm**: lm=TRUE -> draw the linear fit
- **data**: data=TRUE implies draw the data points
- **n**: Should 1 or 2 ellipses be drawn
- **span**: averaging window parameter for the lowess fit
- **iter**: iteration parameter for lowess
- **col**: color of ellipses (default is red)
- **xlab**: label for the x axis
- **ylab**: label for the y axis
- **size**: The size of ellipses in sd units (defaults to 1 and 2)
- **...**: Other parameters for plotting
- **r**: r=1 draws a city block, r=2 is a Euclidean circle, r > 2 tends towards a square
- **main**: title to use when drawing Minkowski circles
- **xl**: stretch the x axis
- **yl**: stretch the y axis

**Details**

Ellipse dimensions are calculated from the correlation between the x and y variables and are scaled as sqrt(1+r) and sqrt(1-r). They are then scaled as size[1] and size[2] standard deviation units. To scale for 95 and 99 percent confidence use c(1.64,2.32)
error.bars

Description

One of the many functions in R to plot means and confidence intervals. Can be done using barplots if desired. Can also be combined with such functions as boxplot to summarize distributions. Means and standard errors are calculated from the raw data using `describe`. Alternatively, plots of means +/- one standard deviation may be drawn.

Usage

```r
derror.bars(x, stats=NULL, data=NULL, group=NULL, ylab = "Dependent Variable", xlab="Independent Variable", main=NULL, eyes=TRUE, ylim = NULL, xlim=NULL, alpha=.05, sd=FALSE, labels = NULL, pos = NULL, arrow.len = .05, arrow.col="black", add = FALSE, bars=FALSE, within=FALSE, col="blue", density=-10,...)
derror.bars.tab(t, way="columns", raw=FALSE, col=c('blue', 'red'),...)
```
Arguments

- **x**: A data frame or matrix of raw data OR, a formula of the form DV ~ IV
- **t**: A table of frequencies
- **stats**: Alternatively, a data.frame of descriptive stats from (e.g., describe)
- **data**: If using formula input, specify the object where the data may found
- **group**: If not null, then do error.bars.by syntax
- **ylab**: y label
- **xlab**: x label
- **main**: title for figure
- **ylim**: if specified, the limits for the plot, otherwise based upon the data
- **xlim**: if specified, the x limits for the plot, otherwise c(.5,nvar + .5)
- **eyes**: should ‘cats eyes’ plots be drawn
- **alpha**: alpha level of confidence interval – defaults to 95% confidence interval
- **sd**: if TRUE, draw one standard deviation instead of standard errors at the alpha level
- **labels**: X axis label
- **pos**: where to place text: below, left, above, right
- **arrow.len**: How long should the top of the error bars be?
- **arrow.col**: What color should the error bars be?
- **add**: add=FALSE, new plot, add=TRUE, just points and error bars
- **bars**: bars=TRUE will draw a bar graph if you really want to do that
- **within**: should the error variance of a variable be corrected by 1-SMC?
- **col**: color(s) of the catseyes. Defaults to blue.
- **density**: If negative, solid colors, if positive, how many lines to draw
- **way**: Percentages are based upon the row totals (default) column totals, or grand total of the data Table
- **raw**: If raw is FALSE, display the graphs in terms of probability, raw TRUE displays the data in terms of raw counts
- **...**: other parameters to pass to the plot function, e.g., typ="b" to draw lines, lty="dashed" to draw dashed lines

Details

Drawing the mean +/- a confidence interval is a frequently used function when reporting experimental results. By default, the confidence interval is 1.96 standard errors of the t-distribution.

If within=TRUE, the error bars are corrected for the correlation with the other variables by reducing the variance by a factor of (1-smc). This allows for comparisons between variables.

The error bars are normally calculated from the data using the describe function. If, alternatively, a matrix of statistics is provided with column headings of values, means, and se, then those values will be used for the plot (using the stats option). If n is included in the matrix of statistics, then the distribution is drawn for a t distribution for n-1 df. If n is omitted (NULL) or is NA, then the distribution will be a normal distribution.

If sd is TRUE, then the error bars will represent one standard deviation from the mean rather than be a function of alpha and the standard errors.
See the last two examples for the case of plotting data with statistics from another function. Alternatively, `error.bars.tab` will take tabulated data and convert to either row, column or overall percentages, and then plot these as percentages with the equivalent standard error (based upon $\sqrt{pq/N}$).

In August, 2018, the functionality of `error.bars` and `error.bars.by` were combined so that if groups are specified, then the error bars are done by group. Furthermore, if the x variable is a formula of the form $DV \sim IV$, then `error.bars.by` is called to do the plotting.

Value

Graphic output showing the means + x

These confidence regions are based upon normal theory and do not take into account any skew in the variables. More accurate confidence intervals could be found by resampling.

The error.bars.tab function will return (invisibly) the cell means and standard errors.

Author(s)

William Revelle

See Also

`error.crosses` for two way error bars, `error.bars.by` for error bars for different groups as well as `error.dots`.

The `error.bars.by` is useful for showing the results of one or two way ANOVAs in that it will display means and CIs for one or more DVs for one or two IVs.

In addition, as pointed out by Jim Lemon on the R-help news group, error bars or confidence intervals may be drawn using

error.bars.by

Plot means and confidence intervals for multiple groups

Description

One of the many functions in R to plot means and confidence intervals. Meant mainly for demonstration purposes for showing the probability of replication from multiple samples. Can also be combined with such functions as boxplot to summarize distributions. Means and standard errors for each group are calculated using describeBy.

Usage

error.bars.by(x, group, data=NULL, by.var=FALSE, x.cat=TRUE, ylab =NULL, xlab=NULL, main=NULL, ylim= NULL, xlim=NULL, eyes=TRUE, alpha=.05, sd=FALSE, labels=NULL, v.labels=NULL, pos=NULL, arrow.len=.05, add=FALSE, bars=FALSE, within=FALSE, colors=c("black","blue","red"), lty, lines=TRUE, legend=0, pch, density=-10, ...)

Arguments

x A data frame or matrix
group A grouping variable
data If using formula input, the data file must be specified
by.var A different line for each group (default) or each variable
x.cat Is the grouping variable categorical (TRUE) or continuous (FALSE
ylab y label
xlab x label
main title for figure
ylim if specified, the y limits for the plot, otherwise based upon the data
xlim if specified, the x limits for the plot, otherwise based upon the data
eyes Should ‘cats eyes’ be drawn
alpha alpha level of confidence interval. Default is 1- alpha =95% confidence interval
sd sd=TRUE will plot Standard Deviations instead of standard errors
labels X axis label
v.labels For a bar plot legend, these are the variable labels, for a line plot, the labels of the grouping variable.
pos where to place text: below, left, above, right
arrow.len How long should the top of the error bars be?
add add=FALSE, new plot, add=TRUE, just points and error bars
bars Draw a barplot with error bars rather than a simple plot of the means
within Should the s.e. be corrected by the correlation with the other variables?
colors groups will be plotted in different colors (mod n.groups). See the note for how to make them transparent.
lty line type may be specified in the case of not plotting by variables
lines: By default, when plotting different groups, connect the groups with a line of type = lty. If lines is FALSE, then do not connect the groups.

legend: Where should the legend be drawn: 0 (do not draw it), 1 = lower right corner, 2 = bottom, 3 ... 8 continue clockwise, 9 is the center.

pch: The first plot symbol to use. Subsequent groups are pch + group.

density: How many lines/inch should fill the cats eyes. If missing, non-transparent colors are used. If negative, transparent colors are used.

... other parameters to pass to the plot function e.g., lty="dashed" to draw dashed lines.

Details

Drawing the mean +/- a confidence interval is a frequently used function when reporting experimental results. By default, the confidence interval is 1.96 standard errors (adjusted for the t-distribution).

Improved/modified in August, 2018 to allow formula input (see examples) as well as to more properly handle multiple groups.

Following a request for better labeling of the grouping variables, the v.lab option is implemented for line graphs as well as bar graphs. Note that if using multiple grouping variables, the labels are for the variable with the most levels (which should be the first one.)

This function was originally just a wrapper for `error.bars` but has been written to allow groups to be organized either as the x axis or as separate lines.

If desired, a barplot with error bars can be shown. Many find this type of plot to be uninformative (e.g., https://biostat.mc.vanderbilt.edu/DynamitePlots ) and recommend the more standard dot plot.

Note in particular, if choosing to draw barplots, the starting value is 0.0 and setting the ylim parameter can lead to some awkward results if 0 is not included in the ylim range. Did you really mean to draw a bar plot in this case?

For up to three groups, the colors are by default "black", "blue" and "red". For more than 3 groups, they are by default rainbow colors with an alpha factor (transparency) of .5.

To make colors semitransparent, set the density to a negative number. See the last example.

Value

Graphic output showing the means + x% confidence intervals for each group. For ci=1.96, and normal data, this will be the 95% confidence region. For ci=1, the 68% confidence region.

These confidence regions are based upon normal theory and do not take into account any skew in the variables. More accurate confidence intervals could be found by resampling.

The results of describeBy are reported invisibly.

scores <- scoreItems(keys,bfis,min=1,max=6) # set the right limits for item reversals
# now draw the results by age
error.bars.by(scores$scores,round(bfis$age/10)*10,by.var=TRUE,
              main="BFI age trends",legend=3,labels=colnames(scores$scores),
              xlab="Age",ylab="Mean item score")
error.bars.by(scores$scores,round(bfis$age/10)*10,by.var=TRUE,
              main="BFI age trends",legend=3,labels=colnames(scores$scores),
              xlab="Age",ylab="Mean item score",density=-10)
error.crosses

Description

Given two vectors of data (X and Y), plot the means and show standard errors in both X and Y directions.

Usage

```r
error.crosses(x,y,labels=NULL,main=NULL,xlim=NULL,ylim= NULL, xlab=NULL,ylab=NULL,pos=NULL,offset=1,arrow.len=.2,alpha=.05,sd=FALSE,add=FALSE, colors=NULL,col.arrows=NULL,col.text=NULL,...)
```

Arguments

- `x`: A vector of data or summary statistics (from Describe)
- `y`: A second vector of data or summary statistics (also from Describe)
- `labels`: the names of each pair – defaults to rownames of x
- `main`: The title for the graph
- `xlim`: xlim values if desired– defaults to min and max mean(x) +/- 2 se
- `ylim`: ylim values if desired – defaults to min and max mean(y) +/- 2 se
- `xlab`: label for x axis – grouping variable 1
- `ylab`: label for y axis – grouping variable 2
- `pos`: Labels are located where with respect to the mean?
- `offset`: Labels are then offset from this location
- `arrow.len`: Arrow length
- `alpha`: alpha level of error bars
- `sd`: if sd is TRUE, then draw means +/- 1 sd
- `add`: if TRUE, overlay the values with a prior plot
- `colors`: What color(s) should be used for the plot character? Defaults to black
- `col.arrows`: What color(s) should be used for the arrows – defaults to colors
- `col.text`: What color(s) should be used for the text – defaults to colors
- `...`: Other parameters for plot

Details

For an example of two way error bars describing the effects of mood manipulations upon positive and negative affect, see [https://personality-project.org/revelle/publications/happy-sad-appendix/FIG.A-6.pdf](https://personality-project.org/revelle/publications/happy-sad-appendix/FIG.A-6.pdf)

The second example shows how error crosses can be done for multiple variables where the grouping variable is found dynamically. The errorCircles example shows how to do this in one step.

William Revelle
<revelle@northwestern.edu>
See Also

To draw error bars for single variables error.bars, or by groups error.bars.by, or to find descriptive statistics describe or descriptive statistics by a grouping variable describeBy and statsBy.

A much improved version is now called errorCircles.

Examples

```r
#just draw one pair of variables
desc <- describe(attitude)
x <- desc[1,]
y <- desc[2,]
error.crosses(x,y,xlab=rownames(x),ylab=rownames(y))

#now for a bit more complicated plotting
data(psychTools::bfi)
desc <- describeBy(psychTools::bfi[1:25],psychTools::bfi$gender) #select a high and low group
error.crosses(desc$’1’,desc$’2’,ylab=’female scores’,
               xlab=’male scores’,main=’BFI scores by gender’)
abline(a=0,b=1)

#do it from summary statistics (using standard errors)
g1.stats <- data.frame(n=c(10,20,30),mean=c(10,12,18),se=c(2,3,5))
g2.stats <- data.frame(n=c(15,20,25),mean=c(6,14,15),se =c(1,2,3))
error.crosses(g1.stats,g2.stats)

#Or, if you prefer to draw +/- 1 sd. instead of 95% confidence
g1.stats <- data.frame(n=c(10,20,30),mean=c(10,12,18),sd=c(2,3,5))
g2.stats <- data.frame(n=c(15,20,25),mean=c(6,14,15),sd =c(1,2,3))
error.crosses(g1.stats,g2.stats,sd=TRUE)

#and seem even fancy plotting: This is taken from a study of mood
#four films were given (sad, horror, neutral, happy)
#with a pre and post test
data(psychTools::affect)
colors <- c(“black”,”red”,”green”,”blue”)
films <- c(“Sad”,”Horror”,”Neutral”,”Happy”)
affect.mat <- describeBy(psychTools::affect[10:17],psychTools::affect$Film,mat=TRUE)
error.crosses(affect.mat[c(1:4,17:20),],affect.mat[c(5:8,21:24),],
              labels=films[affect.mat$group1],xlab=’Energetic Arousal’,
ylab=’Tense Arousal’,colors =
colors[affect.mat$group1],pch=16,cex=2)
```

Error.dots

Show a dot.chart with error bars for different groups or variables

Description

Yet one more of the graphical ways of showing data with error bars for different groups. A dot.chart with error bars for different groups or variables is found using from describe, describeBy, statsBy or data from bestScales.
Usage

error.dots(x=NULL, var = NULL, se = NULL, group = NULL, sd = FALSE, effect=NULL ,stats=NULL, head = 12, tail = 12, sort = TRUE, decreasing = TRUE, main = NULL, alpha = 0.05, eyes = FALSE, min.n = NULL, max.labels = 40, labels = NULL, groups = NULL, gdata = NULL, cex = par("cex"), pt.cex = cex, pch = 21, gpch = 21, bg = par("bg"), color = par("fg"), gcolor = par("fg"), lcolor = "gray", xlab = NULL, ylab = NULL, xlim = NULL,add=FALSE,order=NULL, ...)

Arguments

x A data frame or matrix of raw data, or the resulting object from describe, describeBy, statsBy or bestScales
var The variable to show (particularly if doing describeBy or StatsBy plots).
se Source of a standard error
group A grouping variable, if desired. Will group the data on group for one variable (var)
sd if FALSE, confidence intervals in terms of standard errors, otherwise draw one standard deviation
effect Should the data be compared to a specified group (with mean set to 0) in effect size units?
stats A matrix of means and se to use instead of finding them from the data
head The number of largest values to report
tail The number of smallest values to report
sort Sort the groups/variables by value
decreasing Should they be sorted in increasing or decreasing order (from top to bottom)
main The caption for the figure
alpha p value for confidence intervals
eyes Draw catseyes for error limits
min.n If using describeBy or statsBy, what should be the minimum sample size to draw
max.labels Length of labels (truncate after this value)
labels Specify the labels versus find them from the row names
groups ignored
gdata ignored
cex The standard meaning of cex for graphics
pt.cex ignored
pch Plot character
gpch ignored
bg background color
color Color
gcolor ignored
lcolor ignored?
xlab Label the x axis, if NULL, the variable name is used
ylab If NULL, then the group rownames are used
errorCircles

xlim If NULL, then calculated to show nice values
add If TRUE, will add the plot to a previous plot (e.g., from dotchart)
order if sort=TRUE, if order is NULL, sort on values, otherwise, if order is returned from a previous figure, use that order.
... And any other graphic parameters we have forgotten

Details
Adapted from the dot.chart function to include error bars and to use the output of describe, describeBy, statsBy, fa and bestScales. To speed up multiple plots, the function can work from the output of a previous run. Thus describeBy will be done and the results can be show for multiple variables.
If using the add=TRUE option to add an error.dots plot to a dotplot, note that the order of variables in dot plots goes from last to first (highest y value is actually the last value in a vector.) Also note that the xlim parameter should be set to make sure the plots line up correctly.

Value
Returns (invisibily) either a describeBy or describe object as well as the order if sorted

Author(s)
William Revelle

References
Used in particular for showing https://sapa-project.org output.

See Also
describe, describeBy, or statsBy as well as error.bars, error.bars.by, statsBy or bestScales.

Examples
temp <- error.dots(psychTools::bfi[1:25],sort=TRUE, xlab="Mean score for the item, sorted by difficulty")
error.dots(psychTools::bfi[1:25],sort=TRUE, order=temp$order, add=TRUE, eyes=TRUE) #over plot with eyes

error.dots(psychTools::ability,eyes=TRUE, xlab="Mean score for the item")

errorCircles Two way plots of means, error bars, and sample sizes

Description
Given a matrix or data frame, data, find statistics based upon a grouping variable and then plot x and y means with error bars for each value of the grouping variable. If the data are paired (e.g. by gender), then plot means and error bars for the two groups on all variables.
Usage

```r
errorCircles(x, y, data, ydata = NULL, group=NULL, paired = FALSE, labels = NULL,
main = NULL, xlim = NULL, ylim = NULL, xlab = NULL, ylab = NULL, add=FALSE, pos = NULL,
offset = 1, arrow.len = 0.2, alpha = 0.05, sd = FALSE, bars = TRUE, circles = TRUE, 
colors=NULL,col.arrows=NULL,col.text=NULL,circle.size=1, ...)```

Arguments

- `x`: The x variable (by name or number) to plot
- `y`: The y variable (name or number) to plot
- `data`: The matrix or data.frame to use for the x data
- `ydata`: If plotting data from two data.frames, then the y variable of the ydata frame will be used.
- `group`: If specified, then `statsBy` is called first to find the statistics by group
- `paired`: If TRUE, plot all x and y variables for the two values of the grouping variable.
- `labels`: A vector of names
- `main`: Main title for plot
- `xlim`: xlim values if desired– defaults to min and max mean(x) +/- 2 se
- `ylim`: ylim values if desired – defaults to min and max mean(y) +/- 2 se
- `xlab`: label for x axis – grouping variable 1
- `ylab`: label for y axis – grouping variable 2
- `add`: If TRUE, add to the prior plot
- `pos`: Labels are located where with respect to the mean?
- `offset`: Labels are then offset from this location
- `arrow.len`: Arrow length
- `alpha`: alpha level of error bars
- `sd`: if sd is TRUE, then draw means +/- 1 sd
- `bars`: Should error.bars be drawn for both x and y
- `circles`: Should circles representing the relative sample sizes be drawn?
- `colors`: Plot the points using colors – default is black
- `col.text`: What color for the text labels (defaults to colors)
- `col.arrows`: What color should the arrows and circles be? Defaults to colors
- `circle.size`: A scaling parameter for the error.circles. Defaults to 1, but can be adjusted downwards to make them less intrusive.
- `...`: Other parameters for plot

Details

When visualizing the effect of an experimental manipulation or the relationship of multiple groups, it is convenient to plot their means as well as their confidence regions in a two dimensional space. The diameter of the enclosing circle (ellipse) scales as $1/\sqrt{N}$ * the maximum standard error of all variables. That is to say, the area of the ellipse reflects sample size.

Value

If the group variable is specified, then the statistics from `statsBy` are (invisibly) returned.
Note

Basically this is a combination (and improvement) of statsBy with error.crosses. Can also serve some of the functionality of error.bars.by (see the last example).

Perform and Exploratory Structural Equation Model (ESEM) by using factor extension techniques
Description

Structural Equation Modeling (SEM) is a powerful tool for confirming multivariate structures and is well done by the lavaan, sem, or OpenMx packages. Because they are confirmatory, SEM models test specific models. Exploratory Structural Equation Modeling (ESEM), on the other hand, takes a more exploratory approach. By using factor extension, it is possible to extend the factors of one set of variables (X) into the variable space of another set (Y). Using this technique, it is then possible to estimate the correlations between the two sets of latent variables, much the way normal SEM would do. Based upon exploratory factor analysis (EFA) this approach provides a quick and easy approach to do exploratory structural equation modeling.

Usage

```r
esem(r, varsX, varsY, nfX = 1, nfY = 1, n.obs = NULL, fm = "minres",
      rotate = "oblimin", plot = TRUE, cor = "cor", use = "pairwise", weight=NULL, ...)
esem.diagram(esem=NULL, labels=NULL, cut=.3, errors=FALSE, simple=TRUE,
             regression=FALSE, lr=TRUE, digits=1, e.size=.1, adj=2,
             main="Exploratory Structural Model", ...)
interbattery(r, varsX, varsY, nfX = 1, nfY = 1, n.obs = NULL, cor = "cor",
            use = "pairwise", weight=NULL)
```

Arguments

- `r`: A correlation matrix or a raw data matrix suitable for factor analysis
- `varsX`: The variables defining set X
- `varsY`: The variables defining set Y
- `nfX`: The number of factors to extract for the X variables
- `nfY`: The number of factors to extract for the Y variables
- `n.obs`: Number of observations (needed for eBIC and chi square), can be ignored.
- `fm`: The factor method to use, e.g., "minres", "mle" etc. (see fa for details)
- `rotate`: Which rotation to use. (see fa for details)
- `plot`: If TRUE, draw the esem.diagram
- `cor`: What options for to use for correlations (see fa for details)
- `use`: "pairwise" for pairwise complete data, for other options see cor
- `weight`: Weights to apply to cases when finding wt.cov
- `...`: other parameters to pass to fa or to esem.diagram functions.
- `esem`: The object returned from esem and passed to esem.diagram
- `labels`: Variable labels
- `cut`: Loadings with abs(loading) > cut will be shown
- `simple`: Only the biggest loading per item is shown
- `errors`: include error estimates (as arrows)
- `e.size`: size of ellipses (adjusted by the number of variables)
- `digits`: Round coefficient to digits
- `adj`: loadings are adjusted by factor number mod adj to decrease likelihood of overlap
- `main`: Graphic title, defaults to "Exploratory Structural Model"
- `lr`: draw the graphic left to right (TRUE) or top to bottom (FALSE)
- `regression`: Not yet implemented
Details

Factor analysis as implemented in \texttt{fa} attempts to summarize the covariance (correlational) structure of a set of variables with a small set of latent variables or “factors”. This solution may be ‘extended’ into a larger space with more variables without changing the original solution (see \texttt{fa.extension}.

Similarly, the factors of a second set of variables (the Y set) may be extended into the original (X) set. Doing so allows two independent measurement models, a measurement model for X and a measurement model for Y. These two sets of latent variables may then be correlated for an Exploratory Structural Equation Model. (This is exploratory because it is based upon exploratory factor analysis (EFA) rather than a confirmatory factor model (CFA) using more traditional Structural Equation Modeling packages such as \texttt{sem}, \texttt{lavaan}, or \texttt{Mx}.)

Although the output seems very similar to that of a normal EFA using \texttt{fa}, it is actually two independent factor analyses (of the X and the Y sets) that are then mutually extended into each other. That is, the loadings and structure matrices from sets X and Y are merely combined, and the correlations between the two sets of factors are found.

Interbattery factor analysis was developed by Tucker (1958) as a way of comparing the factors in common to two batteries of tests. (Currently under development and not yet complete). Using some straightforward linear algebra it is easy to find the factors of the intercorrelations between the two sets of variables. This does not require estimating communalities and is highly related to the procedures of canonical correlation.

The difference between the esem and the interbattery approach is that the first factors the X set and then relates those factors to factors of the Y set. Interbattery factor analysis, on the other hand, tries to find one set of factors that links both sets but is still distinct from factoring both sets together.

Value

| communality | The amount of variance in each of the X and Y variables accounted for by the total model. |
| sumsq | The amount of variance accounted for by each factor – independent of the other factors. |
| dof | Degrees of freedom of the model |
| null.dof | Degrees of freedom of the null model (the correlation matrix) |
| ENull | chi square of the null model |
| chi | chi square of the model. This is found by examining the size of the residuals compared to their standard error. |
| rms | The root mean square of the residuals. |
| nh | Harmonic sample size if using min.chi for factor extraction. |
| EPVAL | Probability of the Empirical Chi Square given the hypothesis of an identity matrix. |
| crms | Adjusted root mean square residual |
| EBIC | When normal theory fails (e.g., in the case of non-positive definite matrices), it useful to examine the empirically derived EBIC based upon the empirical $\chi^2 - 2 \text{df}$. |
| ESABIC | Sample size adjusted empirical BIC |
| fit | sum of squared residuals versus sum of squared original values |
| fit.off | fit applied to the off diagonal elements |
| sd | standard deviation of the residuals |
| factors | Number of factors extracted |
esem

complexity  Item complexity
n.obs      Number of total observations
loadings   The factor pattern matrix for the combined X and Y factors
Structure  The factor structure matrix for the combined X and Y factors
loadsX     Just the X set of loadings (pattern) without the extension variables.
loadsY     Just the Y set of loadings (pattern) without the extension variables.
PhiX       The correlations of the X factors
PhiY       the correlations of the Y factors
Phi        the correlations of the X and Y factors within the selves and across sets.
fm         The factor method used
fx         The complete factor analysis output for the X set
fy         The complete factor analysis output for the Y set
residual   The residual correlation matrix (R - model). May be examined by a call to residual().
Call       Echo back the original call to the function.
model      model code for SEM and for lavaan to do subsequent confirmatory modeling

Note
Developed September, 2016, revised December, 2018 to produce code for lavaan and sem. the esem and esem.diagram functions. Suggestions or comments are most welcome.

fa

Exploratory Factor analysis using MinRes (minimum residual) as well as EFA by Principal Axis, Weighted Least Squares or Maximum Likelihood

Description

Among the many ways to do latent variable exploratory factor analysis (EFA), one of the better is to use Ordinary Least Squares (OLS) to find the minimum residual (minres) solution. This produces solutions very similar to maximum likelihood even for badly behaved matrices. A variation on minres is to do weighted least squares (WLS). Perhaps the most conventional technique is principal axes (PAF). An eigen value decomposition of a correlation matrix is done and then the communalities for each variable are estimated by the first n factors. These communalities are entered onto the diagonal and the procedure is repeated until the sum(diag(r)) does not vary. Yet another estimate procedure is maximum likelihood. For well behaved matrices, maximum likelihood factor analysis
(either in the fa or in the factanal function) is probably preferred. Bootstrapped confidence intervals of the loadings and interfactor correlations are found by fa with n.iter > 1.

**Usage**

```r
fa(r,nfactors=1,n.obs = NA,n.iter=1, rotate="oblimin", scores="regression", residuals=FALSE, SMC=TRUE, covar=FALSE,missing=FALSE,impute="median", min.err = 0.001, max.iter = 50,symmetric=TRUE, warnings=TRUE, fm="minres", alpha=.1,p=.05,oblique.scores=FALSE,np.obs=NULL,use="pairwise",cor="cor", correct=.5,weight=NULL,...)
```

```r
fac(r,nfactors=1,n.obs = NA, rotate="oblimin", scores="tenBerge", residuals=FALSE, SMC=TRUE, covar=FALSE,missing=FALSE,impute="median",min.err = 0.001, max.iter=50,symmetric=TRUE,warnings=TRUE,fm="minres",alpha=.1, oblique.scores=FALSE,np.obs=NULL,use="pairwise",cor="cor",correct=.5, weight=NULL,...)
```

```r
fa.sapa(r,nfactors=1,n.obs = NA,n.iter=1,rotate="oblimin",scores="regression", residuals=FALSE,SMC=TRUE,covar=FALSE,missing=FALSE,impute="median",min.err = .001, max.iter=50,symmetric=TRUE,warnings=TRUE,fm="minres",alpha=.1, np.obs=NULL,use="pairwise",cor="cor",correct=.5,weight=NULL, frac=.1,...)
```

**Arguments**

- **r**
  A correlation or covariance matrix or a raw data matrix. If raw data, the correlation matrix will be found using pairwise deletion. If covariances are supplied, they will be converted to correlations unless the covar option is TRUE.

- **nfactors**
  Number of factors to extract, default is 1

- **n.obs**
  Number of observations used to find the correlation matrix if using a correlation matrix. Used for finding the goodness of fit statistics. Must be specified if using a correlation matrix and finding confidence intervals.

- **np.obs**
  The pairwise number of observations. Used if using a correlation matrix and asking for a minchi solution.

- **rotate**
  "none", "varimax", "quartimax", "bentlerT", "equamax", "varimin", "geominT" and "bifactor" are orthogonal rotations. "Promax", "promax", "oblimin", "simplicmax", "bentlerQ", "geominQ" and "biquartimin" and "cluster" are possible oblique transformations of the solution. The default is to do a oblimin transformation, although versions prior to 2009 defaulted to varimax. SPSS seems to do a Kaiser normalization before doing Promax, this is done here by the call to "promax" which does the normalization before calling Promax in GPArotation.

- **n.iter**
  Number of bootstrap iterations to do in fa or fa.poly

- **residuals**
  Should the residual matrix be shown

- **scores**
  the default="regression" finds factor scores using regression. Alternatives for estimating factor scores include simple regression ("Thurstone"), correlaton preserving ("tenBerge") as well as "Anderson" and "Bartlett" using the appropriate algorithms (factor.scores). Although scores="tenBerge" is probably preferred for most solutions, it will lead to problems with some improper correlation matrices.
SMC

Use squared multiple correlations (SMC=TRUE) or use 1 as initial communality estimate. Try using 1 if imaginary eigen values are reported. If SMC is a vector of length the number of variables, then these values are used as starting values in the case of fm='pa'.

covar

if covar is TRUE, factor the covariance matrix, otherwise factor the correlation matrix

missing

if scores are TRUE, and missing=TRUE, then impute missing values using either the median or the mean

impute

"median" or "mean" values are used to replace missing values

min.err

Iterate until the change in communalities is less than min.err

max.iter

Maximum number of iterations for convergence

symmetric

symmetric=TRUE forces symmetry by just looking at the lower off diagonal values

warnings

warnings=TRUE => warn if number of factors is too many

fm

Factoring method fm="minres" will do a minimum residual as will fm="uls". Both of these use a first derivative. fm="ols" differs very slightly from "minres" in that it minimizes the entire residual matrix using an OLS procedure but uses the empirical first derivative. This will be slower. fm="wls" will do a weighted least squares (WLS) solution, fm="gls" does a generalized weighted least squares (GLS), fm="pa" will do the principal factor solution, fm="ml" will do a maximum likelihood factor analysis. fm="minchi" will minimize the sample size weighted chi square when treating pairwise correlations with different number of subjects per pair. fm="minrank" will do a minimum rank factor analysis. "old.min" will do minimal residual the way it was done prior to April, 2017 (see discussion below). fm="alpha" will do alpha factor analysis as described in Kaiser and Coffey (1965)

alpha

alpha level for the confidence intervals for RMSEA

p

if doing iterations to find confidence intervals, what probability values should be found for the confidence intervals

oblique.scores

When factor scores are found, should they be based on the structure matrix (default) or the pattern matrix (oblique.scores=TRUE). Now it is always false. If you want oblique factor scores, use tenBerge.

weight

If not NULL, a vector of length n.obs that contains weights for each observation. The NULL case is equivalent to all cases being weighted 1.

use

How to treat missing data, use="pairwise" is the default. See cor for other options.

cor

How to find the correlations: "cor" is Pearson", "cov" is covariance, "tet" is tetrachoric, "poly" is polychoric, "mixed" uses mixed cor for a mixture of tetrachorics, polychorics, Pearsons, biserials, and polyserials, Yuleb is Yulebonett, Yuleq and YuleY are the obvious Yule coefficients as appropriate

correct

When doing tetrachoric, polycoric, or mixed cor, how should we treat empty cells. (See the discussion in the help for tetrachoric.)

frac

The fraction of data to sample n.iter times if showing stability across sample sizes

...
Factor analysis is an attempt to approximate a correlation or covariance matrix with one of lesser rank. The basic model is that $R_n \approx F_kF_k^T + U^2$ where $k$ is much less than $n$. There are many ways to do factor analysis, and maximum likelihood procedures are probably the most commonly preferred (see `factanal`). The existence of uniquenesses is what distinguishes factor analysis from principal components analysis (e.g., `principal`). If variables are thought to represent a “true” or latent part then factor analysis provides an estimate of the correlations with the latent factor(s) representing the data. If variables are thought to be measured without error, then principal components provides the most parsimonious description of the data.

Factor loadings will be smaller than component loadings for the later reflect unique error in each variable. The off diagonal residuals for a factor solution will be superior (smaller) that of a component model. Factor loadings can be thought of as the asymptotic component loadings as the number of variables loading on each factor increases.

The `fa` function will do factor analyses using one of six different algorithms: minimum residual (minres, aka ols, uls), principal axes, alpha factoring, weighted least squares, minimum rank, or maximum likelihood.

Principal axes factor analysis has a long history in exploratory analysis and is a straightforward procedure. Successive eigenvalue decompositions are done on a correlation matrix with the diagonal replaced with $\text{diag}(FF')$ until $\sum(\text{diag}(FF'))$ does not change (very much). The current limit of max.iter =50 seems to work for most problems, but the Holzinger-Harmon 24 variable problem needs about 203 iterations to converge for a 5 factor solution.

Not all factor programs that do principal axes do iterative solutions. The example from the SAS manual (Chapter 33) is such a case. To achieve that solution, it is necessary to specify that the max.iter =1. Comparing that solution to an iterated one (the default) shows that iterations improve the solution.

In addition, fm="mle" produces even better solutions for this example. Both the RMSEA and the root mean square of the residuals are smaller than the fm="pa" solution.

However, simulations of multiple problem sets suggest that fm="pa" tends to produce slightly smaller residuals while having slightly larger RMSEAs than does fm="minres" or fm="mle". That is, the sum of squared residuals for fm="pa" seem to be slightly smaller than those found using fm="minres" but the RMSEAs are slightly worse when using fm="pa". That is to say, the "true" minimal residual is probably found by fm="pa".

Following extensive correspondence with Hao Wu and Mikko Ronkko, in April, 2017 the derivative of the minres and uls) fitting was modified. This leads to slightly smaller residuals (appropriately enough for a method claiming to minimize them) than the prior procedure. For consistency with prior analyses, "old.min" was added to give these slightly larger residuals. The differences between old.min and the newer "minres" and "ols" solutions are at the third to fourth decimal, but none the less, are worth noting. For comparison purposes, the fm="ols" uses empirical first derivatives, while uls and minres use equation based first derivatives. The results seem to be identical, but the minres and uls solutions require fewer iterations for larger problems and are faster. Thanks to Hao Wu for some very thoughtful help.

Although usually these various algorithms produce equivalent results, there are several data sets included that show large differences between the methods. Schutz produces Heywood and super Heywood cases, blant leads to very different solutions. In particular, the minres solution produces smaller residuals than does the mle solution, and the factor congruence coefficients show very different solutions.

Principal axes may be used in cases when maximum likelihood solutions fail to converge, although fm="minres" will also do that and tends to produce better (smaller RMSEA) solutions.
The fm="minchi" option is a variation on the "minres" (ols) solution and minimizes the sample size weighted residuals rather than just the residuals. This was developed to handle the problem of data that Massively Missing Completely at Random (MMCAR) which a condition that happens in the SAPA project.

A traditional problem in factor analysis was to find the best estimate of the original communalities in order to speed up convergence. Using the Squared Multiple Correlation (SMC) for each variable will underestimate the original communalities, using 1s will over estimate. By default, the SMC estimate is used. In either case, iterative techniques will tend to converge on a stable solution. If, however, a solution fails to be achieved, it is useful to try again using ones (SMC =FALSE). Alternatively, a vector of starting values for the communalities may be specified by the SMC option. The iterated principal axes algorithm does not attempt to find the best (as defined by a maximum likelihood criterion) solution, but rather one that converges rapidly using successive eigen value decompositions. The maximum likelihood criterion of fit and the associated chi square value are reported, and will be (slightly) worse than that found using maximum likelihood procedures.

The minimum residual (minres) solution is an unweighted least squares solution that takes a slightly different approach. It uses the optim function and adjusts the diagonal elements of the correlation matrix to minimize the squared residual when the factor model is the eigen value decomposition of the reduced matrix. MINRES and PA will both work when ML will not, for they can be used when the matrix is singular. Although before the change in the derivative, the MINRES solution was slightly more similar to the ML solution than is the PA solution. With the change in the derivative of the minres fit, the minres, pa and uls solutions are practically identical. To a great extent, the minres and wls solutions follow ideas in the factanal function with the change in the derivative.

The weighted least squares (wls) solution weights the residual matrix by 1/ diagonal of the inverse of the correlation matrix. This has the effect of weighting items with low communalities more than those with high communalities.

The generalized least squares (gls) solution weights the residual matrix by the inverse of the correlation matrix. This has the effect of weighting those variables with low communalities even more than those with high communalities.

The maximum likelihood solution takes yet another approach and finds those communality values that minimize the chi square goodness of fit test. The fm="ml" option provides a maximum likelihood solution following the procedures used in factanal but does not provide all the extra features of that function. It does, however, produce more expansive output.

The minimum rank factor model (MRFA) roughly follows ideas by Shapiro and Ten Berge (2002) and Ten Berge and Kiers (1991). It makes use of the glh.algebraic procedure contributed by Andreas Moltner. MRFA attempts to extract factors such that the residual matrix is still positive semi-definite. This version is still being tested and feedback is most welcome.

Alpha factor analysis finds solutions based upon a correlation matrix corrected for communalities and then rescales these to the original correlation matrix. This procedure is described by Kaiser and Coffey, 1965.

Test cases comparing the output to SPSS suggest that the PA algorithm matches what SPSS calls uls, and that the wls solutions are equivalent in their fits. The wls and gls solutions have slightly larger eigen values, but slightly worse fits of the off diagonal residuals than do the minres or maximum likelihood solutions. Comparing the results to the examples in Harman (1976), the PA solution with no iterations matches what Harman calls Principal Axes (as does SAS), while the iterated PA solution matches his minres solution. The minres solution found in psych tends to have slightly smaller off diagonal residuals (as it should) than does the iterated PA solution.

Although for items, it is typical to find factor scores by scoring the salient items (using, e.g., scoreItems) factor scores can be estimated by regression as well as several other means. There are multiple approaches that are possible (see Grice, 2001) and one taken here was developed by
tenBerge et al. (see \texttt{factor.scores}). The alternative, which will match \texttt{factanal} is to find the scores using regression – Thurstone’s least squares regression where the weights are found by $W = R^{\dagger} - 1)S$ where $R$ is the correlation matrix of the variables ans $S$ is the structure matrix. Then, factor scores are just $F_s = XW$.

In the oblique case, the factor loadings are referred to as Pattern coefficients and are related to the Structure coefficients by $S = P\Phi$ and thus $P = S\Phi^{-1}$. When estimating factor scores, \texttt{fa} and \texttt{factanal} differ in that \texttt{fa} finds the factors from the Structure matrix while \texttt{factanal} seems to do it from the Pattern matrix. Thus, although in the orthogonal case, \texttt{fa} and \texttt{factanal} agree perfectly in their factor score estimates, they do not agree in the case of oblique factors. Setting \texttt{oblique.scores = TRUE} will produce factor score estimate that match those of \texttt{factanal}.

It is sometimes useful to extend the factor solution to variables that were not factored. This may be done using \texttt{fa.extension}. Factor extension is typically done in the case where some variables were not appropriate to factor, but factor loadings on the original factors are still desired.

For dichotomous items or polytomous items, it is recommended to analyze the tetrachoric or polychoric correlations rather than the Pearson correlations. This may be done by specifying \texttt{cor=\"poly\"} or \texttt{cor=\"tet\"} or \texttt{cor=\"mixed\"} if the data have a mixture of dichotomous, polytomous, and continuous variables.

Analysis of dichotomous or polytomous data may also be done by using \texttt{irt.fa} or simply setting the \texttt{cor=\"poly\"} option. In the first case, the factor analysis results are reported in Item Response Theory (IRT) terms, although the original factor solution is returned in the results. In the later case, a typical factor loadings matrix is returned, but the tetrachoric/polychoric correlation matrix and item statistics are saved for reanalysis by \texttt{irt.fa}. (See also the \texttt{mixed.cor} function to find correlations from a mixture of continuous, dichotomous, and polytomous items.)

Of the various rotation/transformation options, varimax, Varimax, quartimax, bentlerT, geominT, and bifactor do orthogonal rotations. Promax transforms obliquely with a target matrix equal to the varimax solution. oblimin, quartimin, simplimax, bentlerQ, geominQ and biquartimin are oblique transformations. Most of these are just calls to the GPArotation package. The “cluster” option does a targeted rotation to a structure defined by the cluster representation of a varimax solution. With the optional “keys” parameter, the “target” option will rotate to a target supplied as a keys matrix. (See \texttt{target.rot}.)

Two additional target rotation options are available through calls to GPArotation. These are the targetQ (oblique) and targetT (orthogonal) target rotations of Michael Browne. See \texttt{target.rot} for more documentation.

The "bifactor" rotation implements the Jennrich and Bentler (2011) bifactor rotation by calling the GPForth function in the GPArotation package and using two functions adapted from the MatLab code of Jennrich and Bentler. This seems to have a problem with local minima and multiple starting values should be used.

There are two varimax rotation functions. One, Varimax, in the GPArotation package does not by default apply Kaiser normalization. The other, varimax, in the stats package, does. It appears that the two rotation functions produce slightly different results even when normalization is set. For consistency with the other rotation functions, Varimax is probably preferred.

The rotation matrix (\texttt{rot.mat}) is returned from all of these options. This is the inverse of the $\Theta$ (theta?) object returned by the GPArotation package. The correlations of the factors may be found by $\Phi = \Theta'\Theta$.

There are two ways to handle dichotomous or polytomous responses: \texttt{fa} with the \texttt{cor=\"poly\"} option which will return the tetrachoric or polychoric correlation matrix, as well as the normal factor analysis output, and \texttt{irt.fa} which returns a two parameter irt analysis as well as the normal \texttt{fa} output.
When factor analyzing items with dichotomous or polytomous responses, the `irt.fa` function provides an Item Response Theory representation of the factor output. The factor analysis results are available, however, as an object in the `irt.fa` output.

`fa.poly` is deprecated, for its functioning is matched by setting `cor="poly"`. It will produce normal factor analysis output but also will save the polychoric matrix (rho) and items difficulties (tau) for subsequent `irt` analyses. `fa.poly` will, by default, find factor scores if the data are available. The correlations are found using either `tetrachoric` or `polychoric` and then this matrix is factored. Weights from the factors are then applied to the original data to estimate factor scores.

The function `fa` will repeat the analysis `n.iter` times on a bootstrapped sample of the data (if they exist) or of a simulated data set based upon the observed correlation matrix. The mean estimate and standard deviation of the estimate are returned and will print the original factor analysis as well as the alpha level confidence intervals for the estimated coefficients. The bootstrapped solutions are rotated towards the original solution using `target.rot`. The factor loadings are z-transformed, averaged and then back transformed. This leads to an error in the case of Heywood cases. The probably better alternative is to just find the mean bootstrapped value and find the confidence intervals based upon the observed range of values. The default is to have `n.iter` = 1 and thus not do bootstrapping.

If using polytomous or dichotomous items, it is perhaps more useful to find the Item Response Theory parameters equivalent to the factor loadings reported in `fa.poly` by using the `irt.fa` function.

Some correlation matrices that arise from using pairwise deletion or from tetrachoric or polychoric matrices will not be proper. That is, they will not be positive semi-definite (all eigen values >= 0). The `cor.smooth` function will adjust correlation matrices (smooth them) by making all negative eigen values slightly greater than 0, rescaling the other eigen values to sum to the number of variables, and then recreating the correlation matrix. See `cor.smooth` for an example of this problem using the `burt` data set.

One reason for this problem when using tetrachorics or polychorics seems to be the adjustment for continuity. Setting `correct=0` turns this off and seems to produce more proper matrices.

For those who like SPSS type output, the measure of factoring adequacy known as the Kaiser-Meyer-Olkin KMO test may be found from the correlation matrix or data matrix using the `KMO` function. Similarly, the Bartlett’s test of Sphericity may be found using the `cortest.bartlett` function.

For those who want to have an object of the variances accounted for, this is returned invisibly by the `print` function. (e.g., `p <- print(fa(ability))$Vaccounted`). This is now returned by the `fa` function as well (e.g. `p <- fa(ability)$Vaccounted`).

The output from the `print.psych.fa` function displays the factor loadings (from the pattern matrix, the h2 (communalities) the u2 (the uniquenesses), com (the complexity of the factor loadings for that variable (see below). In the case of an orthogonal solution, h2 is merely the row sum of the squared factor loadings. But for an oblique solution, it is the row sum of the orthogonal factor loadings (remember, that rotations or transformations do not change the communality).

`fa.sapa` simulates the process of doing SAPA (Synthetic Aperture Personality Assessment). It will do iterative solutions for successive random samples of fractions (frac) of the data set. This allows us to find the stability of solutions for various sample sizes and various sample rates. Need to specify the number of iterations (`n.iter`) as well as the percent of data sampled (frac).

### Value

| values | Eigen values of the common factor solution |
| e.values | Eigen values of the original matrix |
| communality | Communalitity estimates for each item. These are merely the sum of squared factor loadings for that item. |
If using minrank factor analysis, these are the communalities reflecting the total amount of common variance. They will exceed the communality (above) which is the model estimated common variance.

which rotation was requested?

number of observations specified or found

An item by factor (pattern) loading matrix of class “loadings” Suitable for use in other programs (e.g., GPA rotation or factor2cluster. To show these by sorted order, use print.psych with sort=TRUE

Hoffman’s index of complexity for each item. This is just \((\sum a_i^2)^2 \sum_n a_i^4\) where \(a_i\) is the factor loading on the \(i\)th factor. From Hofmann (1978), MBR. See also Pettersson and Turkheimer (2010).

An item by factor structure matrix of class “loadings”. This is just the loadings (pattern) matrix times the factor intercorrelation matrix.

How well does the factor model reproduce the correlation matrix. This is just \(\sum r_{ij}^2 - \sum r_{ij}^2\) (See VSS, ICLUST, and principal for this fit statistic.

how well are the off diagonal elements reproduced?

Degrees of Freedom for this model. This is the number of observed correlations minus the number of independent parameters. Let \(n=Number\ of\ items, \ nf = number\ of\ factors\) then

\[dof = n \ast (n - 1)/2 - n \ast nf + nf \ast (nf - 1)/2\]

Value of the function that is minimized by a maximum likelihood procedures. This is reported for comparison purposes and as a way to estimate chi square goodness of fit. The objective function is

\[f = \log (\text{trace}((FF' + U2)^{-1}R) - \log((FF' + U2)^{-1}R)) - n.\text{items}\]. When using MLE, this function is minimized. When using OLS (minres), although we are not minimizing this function directly, we can still calculate it in order to compare the solution to a MLE fit.

If the number of observations is specified or found, this is a chi square based upon the objective function, \(f\) (see above). Using the formula from factanal (which seems to be Bartlett’s test):

\[\chi^2 = (n.\text{obs} - 1 - (2 \ast p + 5)/6 - (2 \ast factors)/3)) \ast f\]

If \(n.\text{obs} > 0\), then what is the probability of observing a chisquare this large or larger?

If oblique rotations (e.g., using oblimin from the GPArotation package or promax) are requested, what is the interfactor correlation?

The history of the communality estimates (For principal axis only.) Probably only useful for teaching what happens in the process of iterative fitting.

The matrix of residual correlations after the factor model is applied. To display it conveniently, use the residuals command.

When normal theory fails (e.g., in the case of non-positive definite matrices), it useful to examine the empirically derived \(\chi^2\) based upon the sum of the squared residuals * \(N\). This will differ slightly from the MLE estimate which is based upon the fitting function rather than the actual residuals.

This is the sum of the squared (off diagonal residuals) divided by the degrees of freedom. Comparable to an RMSEA which, because it is based upon \(\chi^2\), requires the number of observations to be specified. The rms is an empirical
value while the RMSEA is based upon normal theory and the non-central $\chi^2$ distribution. That is to say, if the residuals are particularly non-normal, the rms value and the associated $\chi^2$ and RMSEA can differ substantially.

crms
rms adjusted for degrees of freedom

RMSEA
The Root Mean Square Error of Approximation is based upon the non-central $\chi^2$ distribution and the $\chi^2$ estimate found from the MLE fitting function. With normal theory data, this is fine. But when the residuals are not distributed according to a noncentral $\chi^2$, this can give very strange values. (And thus the confidence intervals cannot be calculated.) The RMSEA is a conventional index of goodness (badness) of fit but it is also useful to examine the actual rms values.

TLI
The Tucker Lewis Index of factoring reliability which is also known as the non-normed fit index.

BIC
Based upon $\chi^2$ with the assumption of normal theory and using the $\chi^2$ found using the objective function defined above. This is just $\chi^2 - 2df$

eBIC
When normal theory fails (e.g., in the case of non-positive definite matrices), it useful to examine the empirically derived eBIC based upon the empirical $\chi^2 - 2df$.

R2
The multiple R square between the factors and factor score estimates, if they were to be found. (From Grice, 2001). Derived from R2 is is the minimum correlation between any two factor estimates $= 2R2 - 1$.

r.scores
The correlations of the factor score estimates using the specified model, if they were to be found. Comparing these correlations with that of the scores themselves will show, if an alternative estimate of factor scores is used (e.g., the tenBerge method), the problem of factor indeterminacy. For these correlations will not necessarily be the same.

weights
The beta weights to find the factor score estimates. These are also used by the predict.psych function to find predicted factor scores for new cases. These weights will depend upon the scoring method requested.

scores
The factor scores as requested. Note that these scores reflect the choice of the way scores should be estimated (see scores in the input). That is, simple regression ("Thurstone"), correlaton preserving ("tenBerge") as well as "Anderson" and "Bartlett" using the appropriate algorithms (see factor.scores). The correlation between factor score estimates (r.scores) is based upon using the regression/Thurstone approach. The actual correlation between scores will reflect the rotation algorithm chosen and may be found by correlating those scores. Although the scores are found by multiplying the standardize data by the weights matrix, this will not result in standard scores if using regression.

valid
The validity coefficient of course coded (unit weighted) factor score estimates (From Grice, 2001)

score.cor
The correlation matrix of course coded (unit weighted) factor score estimates, if they were to be found, based upon the loadings matrix rather than the weights matrix.

rot.mat
The rotation matrix as returned from GPArotation.

Note
Thanks to Erich Studerus for some very helpful suggestions about various rotation and factor scoring algorithms, and to Gumundur Arnkelsson for suggestions about factor scores for singular matrices.
The fac function is the original fa function which is now called by fa repeatedly to get confidence intervals.

SPSS will sometimes use a Kaiser normalization before rotating. This will lead to different solutions than reported here. To get the Kaiser normalized loadings, use kaiser.

The communality for a variable is the amount of variance accounted for by all of the factors. That is to say, for orthogonal factors, it is the sum of the squared factor loadings (rowwise). The communality is insensitive to rotation. However, if an oblique solution is found, then the communality is not the sum of squared pattern coefficients. In both cases (oblique or orthogonal) the communality is the diagonal of the reproduced correlation matrix where $R_{nn} = P_k \Phi_k P_k'$ where $P$ is the pattern matrix and $\Phi$ is the factor intercorrelation matrix. This is the same, of course to multiplying the pattern by the structure: $R = PS' R = PS'$ where the Structure matrix is $S = \Phi P$. Similarly, the eigen values are the diagonal of the product $k \Phi_k P_k' nn P_k$.

A frequently asked question is why are the factor names of the rotated solution not in ascending order? That is, for example, if factoring the 25 items of the bfi, the factor names are MR2 MR3 MR5 MR1 MR4, rather than the seemingly more logical "MR1" "MR2" "MR3" "MR4" "MR5". This is for pedagogical reasons, in that factors as extracted are orthogonal and are in order of amount of variance accounted for. But when rotated (orthogonally) or transformed (obliquely) the simple structure solution does not preserve that order. The factors are still ordered according to variance accounted for, but because rotation changes how much variance each factor explains, the order may not be the same as the original order. The factor names are, of course, arbitrary, and are kept with the original names to show the effect of rotation/transformation. To give them names associated with their ordinal position, simply paste("F", 1:nf, sep="") where nf is the number of factors. See the last example.

The print function for the fa output will return (invisibly) an object (Vaccounted) that matches the printed output for the variance accounted for by each factor, as well as the cumulative variance, and the percentage of variance accounted for by each factor.

Correction to documentation: as of September, 2014, the oblique.scores option is correctly explained. (It had been backwards.) The default (oblique.scores=FALSE) finds scores based upon the Structure matrix, while oblique.scores=TRUE finds them based upon the pattern matrix. The latter case matches factanal. This error was detected by Mark Seeto.

If the raw data are factored, factors scores are found. By default this will be done using 'regression' but alternatives are available. Although the scores are found by multiplying the standardized data by the weights, if using regression, the resulting factor scores will not necessarily have unit variance.

The minimum residual solution is done by finding those communalities that will minimize the off diagonal residual. The uls solution finds those communalities that minimize the total residuals.

The minres solution has been modified (April, 2107) following suggestions by Hao Wu. Although the fitting function was the minimal residual, the first derivative of the fitting function was incorrect. This has now been modified so that the results match those of SPSS and CEFA. The prior solutions are still available using fm="old.min".

Alpha factoring was added in August, 2017 to add to the numerous alternative models of factoring.

A few more lines of output were added in August 2017 to show the measures of factor adequacy for different rotations. This had been available in the results from factor.scores but now is added to the fa output.

principal for principal components analysis (PCA). PCA will give very similar solutions to factor analysis when there are many variables. The differences become more salient as the number of variables decrease. The PCA and FA models are actually very different and should not be confused. One is a model of the observed variables, the other is a model of latent variables. Although some commercial packages (e.g., SPSS and SAS) refer to both as factor models, they are not. It is incorrect to report doing a factor analysis using principal components.
irt.fa for Item Response Theory analyses using factor analysis, using the two parameter IRT equivalent of loadings and difficulties.
fa.random applies a random intercepts model by removing the mean score for each subject prior to factoring.
VSS will produce the Very Simple Structure (VSS) and MAP criteria for the number of factors, nfactors to compare many different factor criteria.
ICLUST will do a hierarchical cluster analysis alternative to factor analysis or principal components analysis.
factor.scores to find factor scores with alternative options. predict.psych to find predicted scores based upon new data, fa.extension to extend the factor solution to new variables, omega for hierarchical factor analysis with one general factor. codefa.multi for hierarchical factor analysis with an arbitrary number of 2nd order factors.
fa.sort will sort the factor loadings into echelon form. fa.organize will reorganize the factor pattern matrix into any arbitrary order of factors and items.
KMO and cortest.bartlett for various tests that some people like.
factor2cluster will prepare unit weighted scoring keys of the factors that can be used with scoreItems.
fa.lookup will print the factor analysis loadings matrix along with the item “content” taken from a dictionary of items. This is useful when examining the meaning of the factors.
anova.psych allows for testing the difference between two (presumably nested) factor models.
**bassAckward** will perform repeated factorings and organize them in a top-down structure suggested by Goldberg (2006) and Waller (2007).

**Examples**

#using the Harman 24 mental tests, compare a principal factor with a principal components solution
```r
pc <- principal(Harman74.cor$cov, 4, rotate="varimax") #principal components
pa <- fa(Harman74.cor$cov, 4, fm="pa", rotate="varimax") #principal axis
uls <- fa(Harman74.cor$cov, 4, rotate="varimax") #unweighted least squares is minres
wls <- fa(Harman74.cor$cov, 4, fm="wls") #weighted least squares
```

#to show the loadings sorted by absolute value
```r
print(uls, sort=TRUE)
```

#then compare with a maximum likelihood solution using factanal
```r
mle <- factanal(covmat=Harman74.cor$cov, factors=4)
factor.congruence(list(mle, pa, pc, uls, wls))
```

#finally, compare the unrotated factor, ml, uls, and wls solutions
```r
wls <- fa(Harman74.cor$cov, 4, rotate="none", fm="wls")
pa <- fa(Harman74.cor$cov, 4, rotate="none", fm="pa")
minres <- factanal(factors=4, covmat=Harman74.cor$cov, rotation="none")
uls <- fa(Harman74.cor$cov, 4, rotate="none", fm="uls")
factor.congruence(list(minres, mle, pa, wls, uls))
```

#in particular, note the similarity of the mle and min res solutions

#note that the order of factors and the sign of some of factors may differ

#an example of where the ML and PA and MR models differ is found in Thurstone.33.
#compare the first two factors with the 3 factor solution

#colnames(f5$loadings) <- paste("F", 1:5, sep="")
#f5

#Get the variance accounted for object from the print function
```r
p <- print(mr3)
round(p$Vaccounted, 2)
```
Description

Factor analysis or principal components analysis results are typically interpreted in terms of the major loadings on each factor. These structures may be represented as a table of loadings or graphically, where all loadings with an absolute value > some cut point are represented as an edge (path). `fa.diagram` uses the various `diagram` functions to draw the diagram. `fa.graph` generates dot code for external plotting. `fa.rgraph` uses the Rgraphviz package (if available) to draw the graph. `het.diagram` will draw "heterarchy" diagrams of factor/scale solutions at different levels.

Usage

```r
fa.diagram(fa.results, Phi=NULL, fe.results=NULL, sort=TRUE, labels=NULL, cut=.3, simple=TRUE, errors=FALSE, g=FALSE, digits=1, side=2, main, cex=NULL, marg=c(.5,.5,1,.5), adj=1, ic=FALSE, ...)
```

```r
het.diagram(r, levels, cut=.3, digits=2, both=TRUE, main="Heterarchy diagram", l.cex, gap.size,...)
```

```r
extension.diagram(fa.results, Phi=NULL, fe.results=NULL, sort=TRUE, labels=NULL, cut=.3, e.cut=.1, simple=TRUE, e.simple=FALSE, errors=FALSE, g=FALSE, digits=1, side=2, main, cex=NULL, marg=c(.5,.5,1,.5), adj=1, ic=FALSE, ...)
```

```r
fa.graph(fa.results, out.file=NULL, labels=NULL, cut=.3, simple=TRUE, size=c(8,6), node.font=c("Helvetica", 14), edge.font=c("Helvetica", 10), rank.direction=c("RL","TB","LR","BT"), digits=1, main="Factor Analysis", ...)
```

```r
fa.rgraph(fa.results, out.file=NULL, labels=NULL, cut=.3, simple=TRUE, size=c(8,6), node.font=c("Helvetica", 14), edge.font=c("Helvetica", 10), rank.direction=c("RL","TB","LR","BT"), digits=1, main="Factor Analysis", graphviz=TRUE, ...)
```

Arguments

- **fa.results**: The output of factor analysis, principal components analysis, or ICLUST analysis. May also be a factor loading matrix from anywhere.
- **Phi**: Normally not specified (it is found in the FA, pc, or ICLUST solution), this may be given if the input is a loadings matrix.
- **fe.results**: the results of a factor extension analysis (if any)
- **out.file**: If it exists, a dot representation of the graph will be stored here (fa.graph)
- **labels**: Variable labels
- **cut**: Loadings with abs(loading) > cut will be shown
- **e.cut**: extension loadings with abs(loading) > e.cut will be shown
- **simple**: Only the biggest loading per item is shown
- **e.simple**: Only the biggest loading per extension item is shown
- **g**: Does the factor matrix reflect a g (first) factor. If so, then draw this to the left of the variables, with the remaining factors to the right of the variables. It is useful to turn off the simple parameter in this case.
- **ic**: If drawing a cluster analysis result, should we treat it as latent variable model (ic=FALSE) or as an observed variable model (ic=TRUE)
- **r**: A correlation matrix for the het.diagram function
levels A list of the elements in each level
both Should arrows have double heads (in het.diagram)
size graph size
sort sort the factor loadings before showing the diagram
errors include error estimates (as arrows)
e.size size of ellipses
r.size size of rectangles
side on which side should error arrows go?
cex modify font size
l.cex modify the font size in arrows, defaults to cex
gap.size The gap in the arrow for the label. Can be adjusted to compensate for variations in cex or l.cex
marg sets the margins to be wider than normal, returns them to the normal size upon exit
adj how many different positions (1-3) should be used for the numeric labels. Useful if they overlap each other.
node.font what font should be used for nodes in fa.graph
edge.font what font should be used for edges in fa.graph
rank.direction parameter passed to Rgraphviz— which way to draw the graph
digits Number of digits to show as an edgelable
main Graphic title, defaults to "factor analysis" or "factor analysis and extension"
graphviz Should we try to use Rgraphviz for output?
... other parameters

Details

Path diagram representations have become standard in confirmatory factor analysis, but are not yet common in exploratory factor analysis. Representing factor structures graphically helps some people understand the structure.

By default the arrows come from the latent variables to the observed variables. This is, of course, the factor model. However, if the class of the object to be drawn is ‘principal’, then reverse the direction of the arrows, and the ‘latent’ variables are no longer latent, and are shown as boxes. For cluster models, the default is to treat them as factors, but if ic = TRUE, then we treat it as a components model.

fa.diagram does not use Rgraphviz and is the preferred function. fa.graph generates dot code to be used by an external graphics program. It does not have all the bells and whistles of fa.diagram, but these may be done in the external editor.

Hierarchical (bifactor) models may be drawn by specifying the g parameter as TRUE. This allows for an graphical displays of various factor transformations with a bifactor structure (e.g., bifactor and biquartimin. See omega for an alternative way to find these structures.

The het.diagram function will show the case of a hetarchical structure at multiple levels. It can also be used to show the patterns of correlations between sets of scales (e.g., EPI, NEO, BFI). The example is for showing the relationship between 3 sets of 4 variables from the Thurstone data set. The parameters l.cex and gap.size are used to adjust the font size of the labels and the gap in the lines.
extension.diagram will draw a fa.extend result with slightly more control than using fa.diagram or the more generic diagram function.

In fa.rgraph although a nice graph is drawn for the orthogonal factor case, the oblique factor drawing is acceptable, but is better if cleaned up outside of R or done using fa.diagram.

The normal input is taken from the output of either fa or ICLUST. This latter case displays the ICLUST results in terms of the cluster loadings, not in terms of the cluster structure. Actually an interesting option.

It is also possible to just give a factor loading matrix as input. In this case, supplying a Phi matrix of factor correlations is also possible.

It is possible, using fa.graph, to export dot code for an omega solution. fa.graph should be applied to the schmid$sl object with labels specified as the rownames of schmid$sl. The results will need editing to make fully compatible with dot language plotting.

To specify the model for a structural equation confirmatory analysis of the results, use structure.diagram instead.

Value

fa.diagram: A path diagram is drawn without using Rgraphviz. This is probably the more useful function.

fa.rgraph: A graph is drawn using rgraphviz. If an output file is specified, the graph instructions are also saved in the dot language.

fa.graph: the graph instructions are saved in the dot language.

Note

fa.rgraph requires Rgraphviz. Because there are occasional difficulties installing Rgraphviz from Bioconductor in that some libraries are misplaced and need to be relinked, it is probably better to use fa.diagram or fa.graph.

het.diagram(Thurstone,levels=list(1:4,5:8,3:7))
fa.extension

Apply Dwyer's factor extension to find factor loadings for extended variables

Description

Dwyer (1937) introduced a method for finding factor loadings for variables not included in the original analysis. This is basically finding the unattenuated correlation of the extension variables with the factor scores. An alternative, which does not correct for factor reliability was proposed by Gorsuch (1997). Both options are an application of exploratory factor analysis with extensions to new variables. Also useful for finding the validities of variables in the factor space.

Usage

fa.extension(Roe, fo, correct=TRUE)
fa.extend(r, nfactors=1, ov= NULL, ev= NULL, n.obs = NA, np.obs= NULL, correct=TRUE, rotate= "oblimin", SMC=TRUE, warnings=TRUE, fm="minres", alpha=.1, omega=FALSE, ...)

Arguments

Roe
The correlations of the original variables with the extended variables

fo
The output from the fa or omega functions applied to the original variables.

correct
correct=TRUE produces Dwyer’s solution, correct=FALSE produces Gorsuch’s solution

r
A correlation or data matrix with all of the variables to be analyzed by fa.extend

ov
The original variables to factor

ev
The extension variables

nfactors
Number of factors to extract, default is 1

n.obs
Number of observations used to find the correlation matrix if using a correlation matrix. Used for finding the goodness of fit statistics. Must be specified if using a correlaton matrix and finding confidence intervals.

np.obs
Pairwise number of observations. Required if using fm="minchi", suggested in other cases to estimate the empirical goodness of fit.

rotate
"none", "varimax", "quartimax", "bentlerT", "geominT" and "bifactor" are orthogonal rotations. "promax", "oblimin", "simplimax", "bentlerQ", "geominQ" and "biquartimin" and "cluster" are possible rotations or transformations of the solution. The default is to do a oblimin transformation, although versions prior to 2009 defaulted to varimax.

SMC
Use squared multiple correlations (SMC=TRUE) or use 1 as initial communality estimate. Try using 1 if imaginary eigen values are reported. If SMC is a vector of length the number of variables, then these values are used as starting values in the case of fm=’pa’.

warnings
warnings=TRUE => warn if number of factors is too many

fm
factoring method fm="minres" will do a minimum residual (OLS), fm="wls" will do a weighted least squares (WLS) solution, fm="gls" does a generalized weighted least squares (GLS), fm="pa" will do the principal factor solution,
fa.extension

fm="ml" will do a maximum likelihood factor analysis. fm="minchi" will minimize the sample size weighted chi square when treating pairwise correlations with different number of subjects per pair.

alpha

alpha level for the confidence intervals for RMSEA

omega

Do the extension analysis for an omega type analysis

... additional parameters, specifically, keys may be passed if using the target rotation, or delta if using geominQ, or whether to normalize if using Varimax

Details

It is sometimes the case that factors are derived from a set of variables (the Fo factor loadings) and we want to see what the loadings of an extended set of variables (Fe) would be. Given the original correlation matrix Ro and the correlation of these original variables with the extension variables of Roe, it is a straight forward calculation to find the loadings Fe of the extended variables on the original factors. This technique was developed by Dwyer (1937) for the case of adding new variables to a factor analysis without doing all the work over again. But, as discussed by Horn (1973) factor extension is also appropriate when one does not want to include the extension variables in the original factor analysis, but does want to see what the loadings would be anyway. This could be done by estimating the factor scores and then finding the covariances of the extension variables with the factor scores. But if the original data are not available, but just the covariance or correlation matrix is, then the use of fa.extension is most appropriate.

The factor analysis results from either fa or omega functions applied to the original correlation matrix is extended to the extended variables given the correlations (Roe) of the extended variables with the original variables.

fa.extension assumes that the original factor solution was found by the fa function.

For a very nice discussion of the relationship between factor scores, correlation matrices, and the factor loadings in a factor extension, see Horn (1973).

The fa.extend function may be thought of as a "seeded" factor analysis. That is, the variables in the original set are factored, this solution is then extended to the extension set, and the resulting output is presented as if both the original and extended variables were factored together. This may also be done for an omega analysis.

The example of code fa.extend compares the extended solution to a direct solution of all of the variables using factor.congruence.

```
Description

When constructing scales through rational, factorial, or empirical means, it is useful to examine the content of the items that relate most highly to each other (e.g., the factor loadings of `fa.lookup` of a set of items), or to some specific set of criteria (e.g., `bestScales`). Given a dictionary of item content, these routines will sort by factor loading or criteria correlations and display the item content.

Usage

```r
lookup(x, y, criteria=NULL)
fa.lookup(f, dictionary=NULL, digits=2, cut=.0, n=NULL, sort=TRUE)
item.lookup(f, m, dictionary, cut=.3, digits = 2)
keys.lookup(keys.list, dictionary)
lookupFromKeys(keys.list, dictionary, n=1, suppress.names=FALSE)
```

Arguments

- `x` A data matrix or data frame depending upon the function.
- `y` A data matrix or data frame or a vector
- `criteria` Which variables (by name or location) should be the empirical target for bestScales and bestItems. May be a separate object.
- `f` The object returned from either a factor analysis (`fa`) or a principal components analysis (`principal`)
- `keys.list` A list of scoring keys suitable to use for make.keys
- `cut` Return all values in `abs(x[,c1]) > cut`.
- `n` Return the `n` best items per factor (as long as they have their highest loading on that factor)
- `dictionary` A data.frame with rownames corresponding to rownames in the `f$loadings` matrix or colnames of the data matrix or correlation matrix, and entries (may be multiple columns) of item content.
- `m` A data frame of item means
- `digits` round to digits
- `sort` Should the factors be sorted first?
- `suppress.names` In lookupFromKeys, should we suppress the column labels
Details

`fa.lookup` and `lookup` are simple helper functions to summarize correlation matrices or factor loading matrices. `bestItems` will sort the specified column (criteria) of `x` on the basis of the (absolute) value of the column. The return as a default is just the rowname of the variable with those absolute values > cut. If there is a dictionary of item content and item names, then include the contents as a two column (or more) matrix with rownames corresponding to the item name and then as many fields as desired for item content. (See the example dictionary `bfi.dictionary`).

`lookup` is used by `bestItems` and will find values in `c1` of `y` that match those in `x`. It returns those rows of `y` of that match `x`. Suppose that you have a "dictionary" of the many variables in a study but you want to consider a small subset of them in a data set `x`. Then, you can find the entries in the dictionary corresponding to `x` by `lookup(rownames(x),y)` If the column is not specified, then it will match by `rownames(y)`.

`fa.lookup` is used when examining the output of a factor analysis and one wants the corresponding variable names and contents. The returned object may then be printed in LaTeX by using the `df2latex` function with the `char` option set to `TRUE`.

`fa.lookup` will work with output from `fa, pca` or `omega`. For omega output, the items are sorted by the non-general factor loadings.

Similarly, given a correlation matrix, `r`, of the `x` variables, if you want to find the items that most correlate with another item or scale, and then show the contents of that item from the dictionary, `bestItems(r,c1=column number or name of `x`, contents = `y`)`

`item.lookup` combines the output from a factor analysis `fa` with simple descriptive statistics (a data frame of means) with a dictionary. Items are grouped by factor loadings > cut, and then sorted by item mean. This allows a better understanding of how a scale works, in terms of the meaning of the item endorsements.

Value

`bestItems` returns a sorted list of factor loadings or correlations with the labels as provided in the dictionary.

`lookup` is a very simple implementation of the match function.

`fa.lookup` takes a factor/cluster analysis object (or just a keys like matrix), sorts it using `fa.sort` and then matches by row.name to the corresponding dictionary entries.

Note

Although empirical scale construction is appealing, it has the basic problem of capitalizing on chance. Thus, be careful of over interpreting the results unless working with large samples. Iteration and bootstrapping aggregation (bagging) gives information on the stability of the solutions. See `bestScales`

To create a dictionary, create an object with row names as the item numbers, and the columns as the item content. See the `link{bfi.dictionary}` as an example. The `bfi.dictionary` was constructed from a spreadsheet with multiple columns, the first of which was the column names of the `bfi`. See the first (not run) example.

# show the keying information

fa.multi

Multi level (hierarchical) factor analysis

Description

Some factor analytic solutions produce correlated factors which may in turn be factored. If the solution has one higher order, the omega function is most appropriate. But, in the case of multi higher order factors, then the faMulti function will do a lower level factoring and then factor the resulting correlation matrix. Multi level factor diagrams are also shown.

Usage

fa.multi(r, nfactors = 3, nfact2 = 1, n.obs = NA, n.iter = 1, rotate = "oblimin", scores = "regression", residuals = FALSE, SMC = TRUE, covar = FALSE, missing = FALSE, impute = "median", min.err = 0.001, max.iter = 50, symmetric = TRUE, warnings = TRUE, fm = "minres", alpha = 0.1, p = 0.05, oblique.scores = FALSE, np.obs = NULL, use = "pairwise", cor = "cor", ...)
Arguments

The arguments match those of the fa function.

**nfactors** The desired number of factors for the lower level  

**nfact2** The desired number of factors for the higher level  

**n.obs** Number of observations used to find the correlation matrix if using a correlation matrix. Used for finding the goodness of fit statistics. Must be specified if using a correlaton matrix and finding confidence intervals.  

**np.obs** The pairwise number of observations. Used if using a correlation matrix and asking for a minchi solution.  

**rotate** "none", "varimax", "quartimax", "bentlerT", "equamax", "varimin", "geominT" and "bifactor" are orthogonal rotations. "promax", "oblimin", "simplimax", "bentlerQ", "geominQ" and "biquartimin" and "cluster" are possible oblique transformations of the solution. The default is to do a oblimin transformation, although versions prior to 2009 defaulted to varimax.  

**n.iter** Number of bootstrap iterations to do in fa or fa.poly  

**residuals** Should the residual matrix be shown  

**scores** the default="regression" finds factor scores using regression. Alternatives for estimating factor scores include simple regression ("Thurstone"), correlaton preserving ("tenBerge") as well as "Anderson" and "Bartlett" using the appropriate algorithms (see factor.scores). Although scores="tenBerge" is probably preferred for most solutions, it will lead to problems with some improper correlation matrices.  

**SMC** Use squared multiple correlations (SMC=TRUE) or use 1 as initial communality estimate. Try using 1 if imaginary eigen values are reported. If SMC is a vector of length the number of variables, then these values are used as starting values in the case of fm='pa'.  

**covar** if covar is TRUE, factor the covariance matrix, otherwise factor the correlation matrix  

**missing** if scores are TRUE, and missing=TRUE, then impute missing values using either the median or the mean  

**impute** "median" or "mean" values are used to replace missing values  

**min.err** Iterate until the change in communalities is less than min.err  

**max.iter** Maximum number of iterations for convergence  

**symmetric** symmetric=TRUE forces symmetry by just looking at the lower off diagonal values  

**warnings** warnings=TRUE => warn if number of factors is too many  

**fm** factoring method fm="minres" will do a minimum residual (OLS), fm="wls" will do a weighted least squares (WLS) solution, fm="gls" does a generalized weighted least squares (GLS), fm="pa" will do the principal factor solution, fm="ml" will do a maximum likelihood factor analysis. fm="minchi" will minimize the sample size weighted chi square when treating pairwise correlations with different number of subjects per pair.  

**alpha** alpha level for the confidence intervals for RMSEA  

**p** if doing iterations to find confidence intervals, what probability values should be found for the confidence intervals
When factor scores are found, should they be based on the structure matrix (default) or the pattern matrix (oblique.scores=TRUE).

How to treat missing data, use="pairwise" is the default. See cor for other options.

How to find the correlations: "cor" is Pearson", "cov" is covariance, "tet" is tetrachoric, "poly" is polychoric, "mixed" uses mixed cor for a mixture of tetrachorics, polychorics, Pearsons, biserials, and polyserials, Yuleb is Yulebonett, Yuleq and YuleY are the obvious Yule coefficients as appropriate

The results from fa.multi
variable labels
Labels for the factors (not counting g)

fa.parallel
Scree plots of data or correlation matrix compared to random "parallel" matrices

Description
One way to determine the number of factors or components in a data matrix or a correlation matrix is to examine the 'scree' plot of the successive eigenvalues. Sharp breaks in the plot suggest the appropriate number of components or factors to extract. "Parallel" analysis is an alternative technique that compares the scree of factors of the observed data with that of a random data matrix of the same size as the original. This may be done for continuous, dichotomous, or polytomous data using Pearson, tetrachoric or polychoric correlations.

Usage
fa.parallel(x, n.obs=NULL, fm="minres", fa="both", nfactors=1, main="Parallel Analysis Scree Plots", n.iter=20, error.bars=FALSE, se.bars=FALSE, SMC=FALSE, ylab=NULL, show.legend=TRUE, quant=.95, cor="cor", use="pairwise", plot=TRUE, correct=.5)
fa.parallel.poly(x, n.iter=10, SMC=TRUE, fm = "minres", correct=TRUE, sim=FALSE, fa="both", global=TRUE) #deprecated
## S3 method for class 'poly.parallel'
plot(x, show.legend=TRUE, fa="both",...)

Arguments
x A data.frame or data matrix of scores. If the matrix is square, it is assumed to be a correlation matrix. Otherwise, correlations (with pairwise deletion) will be found
n.obs n.obs=0 implies a data matrix/data.frame. Otherwise, how many cases were used to find the correlations.
fm What factor method to use. (minres, ml, uls, wls, gls, pa) See fa for details.
show the eigen values for a principal components (fa="pc") or a principal axis factor analysis (fa="fa") or both principal components and principal factors (fa="both")

The number of factors to extract when estimating the eigen values. Defaults to 1, which was the prior value used.

Number of simulated analyses to perform

How to treat missing data, use="pairwise" is the default”. See cor for other options.

How to find the correlations: "cor" is Pearson”, "cov" is covariance, "tet" is tetrachoric, "poly" is polychoric, "mixed" uses mixed cor for a mixture of tetrachorics, polychorics, Pearson’s, biserials, and polyserials, Yuleb is Yulebonett, Yuleq and YuleY are the obvious Yule coefficients as appropriate. This matches the call to fa

For tetrachoric correlations, should a correction for continuity be applied. (See tetrachoric) If set to 0, then no correction is applied, otherwise, the default is to add .5 observations to the cell.

For continuous data, the default is to resample as well as to generate random normal data. If sim=FALSE, then just show the resampled results. These two results are very similar. This does not make sense in the case of correlation matrix, in which case resampling is impossible. In the case of polychoric or tetrachoric data, in addition to randomizing the real data, should we compare the solution to random simulated data. This will double the processing time, but will basically show the same result.

Should error.bars be plotted (default = FALSE)

Should the error bars be standard errors (se.bars=TRUE) or 1 standard deviation (se.bars=FALSE, the default). With many iterations, the standard errors are very small and some prefer to see the broader range. The default has been changed in 1.7.8 to be se.bars=FALSE to more properly show the range.

SMC=TRUE finds eigen values after estimating communalities by using SMCs. smc = FALSE finds eigen values after estimating communalities with the first factor.

Label for the y axis – defaults to “eigen values of factors and components”, can be made empty to show many graphs

the default is to have a legend. For multiple panel graphs, it is better to not show the legend

if nothing is specified, the empirical eigen values are compared to the mean of the resampled or simulated eigen values. If a value (e.g., quant=.95) is specified, then the eigen values are compared against the matching quantile of the simulated data. Clearly the larger the value of quant, the few factors/components that will be identified.

If doing polychoric analyses (fa.parallel.poly) and the number of alternatives differ across items, it is necessary to turn off the global option

additional plotting parameters, for plot.poly.parallel

By default, fa.parallel draws the eigen value plots. If FALSE, suppresses the graphic output
Details

Cattell's "scree" test is one of most simple tests for the number of factors problem. Horn's (1965) "parallel" analysis is an equally compelling procedure. Other procedures for determining the most optimal number of factors include finding the Very Simple Structure (VSS) criterion (VSS) and Velicer's MAP procedure (included in VSS). Both the VSS and the MAP criteria are included in the nfactors function which also reports the mean item complexity and the BIC for each of multiple solutions. fa.parallel plots the eigen values for a principal components and the factor solution (minres by default) and does the same for random matrices of the same size as the original data matrix. For raw data, the random matrices are 1) a matrix of univariate normal data and 2) random samples (randomized across rows) of the original data.

fa.parallel with the cor=poly option will do what fa.parallel.poly explicitly does: parallel analysis for polychoric and tetrachoric factors. If the data are dichotomous, fa.parallel.poly will find tetrachoric correlations for the real and simulated data, otherwise, if the number of categories is less than 10, it will find polychoric correlations. Note that fa.parallel.poly is slower than fa.parallel because of the complexity of calculating the tetrachoric/polychoric correlations. The functionality of fa.parallel.poly is included in fa.parallel with cor=poly option (etc.) option but the older fa.parallel.poly is kept for those who call it directly.

That is, fa.parallel now will do tetrachorics or polychorics directly if the cor option is set to "tet" or "poly". As with fa.parallel.poly this will take longer.

The means of (ntrials) random solutions are shown. Error bars are usually very small and are suppressed by default but can be shown if requested. If the sim option is set to TRUE (default), then parallel analyses are done on resampled data as well as random normal data. In the interests of speed, the parallel analyses are done just on resampled data if sim=FALSE. Both procedures tend to agree.

As of version 1.5.4, I added the ability to specify the quantile of the simulated/resampled data, and to plot standard deviations or standard errors. By default, this is set to the 95th percentile.

Alternative ways to estimate the number of factors problem are discussed in the Very Simple Structure (Revelle and Rocklin, 1979) documentation (VSS) and include Wayne Velicer's MAP algorithm (Velicer, 1976).

Parallel analysis for factors is actually harder than it seems, for the question is what are the appropriate communalities to use. If communalities are estimated by the Squared Multiple Correlation (SMC) smc, then the eigen values of the original data will reflect major as well as minor factors (see sim.minor to simulate such data). Random data will not, of course, have any structure and thus the number of factors will tend to be biased upwards by the presence of the minor factors.

By default, fa.parallel estimates the communalities based upon a one factor minres solution. Although this will underestimate the communalities, it does seem to lead to better solutions on simulated or real (e.g., the bfi or Harman74) data sets.

For comparability with other algorithms (e.g., the paran function in the paran package), setting smc=TRUE will use smcs as estimates of communalities. This will tend towards identifying more factors than the default option.

Yet another option (suggested by Florian Scharf) is to estimate the eigen values based upon a particular factor model (e.g., specify nfactors > 1).

Printing the results will show the eigen values of the original data that are greater than simulated values.

A sad observation about parallel analysis is that it is sensitive to sample size. That is, for large data sets, the eigen values of random data are very close to 1. This will lead to different estimates of the number of factors as a function of sample size. Consider factor structure of the bfi data set (the first 25 items are meant to represent a five factor model). For samples of 200 or less, parallel analysis
suggests 5 factors, but for 1000 or more, six factors and components are indicated. This is not due to an instability of the eigen values of the real data, but rather the closer approximation to 1 of the random data as n increases.

Although with nfactors=1, 6 factors are suggested, when specifying nfactors =5, parallel analysis of the bfi suggests 12 factors should be extracted!

When simulating dichotomous data in fa.parallel.poly, the simulated data have the same difficulties as the original data. This functionally means that the simulated and the resampled results will be very similar. Note that fa.parallel.poly has functionally been replaced with fa.parallel with the cor="poly" option.

As with many psych functions, fa.parallel has been changed to allow for multicore processing. For running a large number of iterations, it is obviously faster to increase the number of cores to the maximum possible (using the options("mc.cores=n) command where n is determined from detectCores()

Value

A plot of the eigen values for the original data, ntrials of resampling of the original data, and of a equivalent size matrix of random normal deviates. If the data are a correlation matrix, specify the number of observations.

Also returned (invisibly) are:

fa.values The eigen values of the factor model for the real data.
fa.sim The descriptive statistics of the simulated factor models.
pc.values The eigen values of a principal components of the real data.
pc.sim The descriptive statistics of the simulated principal components analysis.
nfact Number of factors with eigen values > eigen values of random data
ncomp Number of components with eigen values > eigen values of random data
values The simulated values for all simulated trials

Note

Although by default the test is applied to the 95th percentile eigen values, this can be modified by setting the quant parameter to any particular quantile. The actual simulated data are also returned (invisibly) in the value object. Thus, it is possible to do descriptive statistics on those to choose a preferred comparision. See the last example (not run) The simulated and resampled data tend to be very similar, so for a slightly cleaner figure, set sim=FALSE.

For relatively small samples with dichotomous data and cor="tet" if some cells are empty, or if the resampled matrices are not positive semi-definite, warnings are issued. this leads to serious problems if using multi.cores (the default if using a Mac). The solution seems to be to not use multi.cores (e.g., options(mc.cores =1) )

Note

Gagan Atreya reports a problem with the multi-core implementation of fa.parallel when running Microsoft Open R. This can be resolved by setMKLthreads(1) to set the number of threads to 1.

Details

Please see the writeup for fa for all of the functionality in these older functions.
### Value

- **values**: Eigen values of the common factor solution
- **e.values**: Eigen values of the original matrix
- **communality**: Communality estimates for each item. These are merely the sum of squared factor loadings for that item.
- **communalities**: If using minrank factor analysis, these are the communalities reflecting the total amount of common variance. They will exceed the communality (above) which is the model estimated common variance.
- **rotation**: which rotation was requested?
- **loadings**: An item by factor (pattern) loading matrix of class “loadings” Suitable for use in other programs (e.g., GPA rotation or factor2cluster. To show these by sorted order, use `print.psych` with sort=TRUE
- **complexity**: Hoffman’s index of complexity for each item. This is just $\frac{(\sum a_i^2)^2}{\sum a_i^4}$ where $a_i$ is the factor loading on the $i$th factor. From Hofmann (1978), MBR. See also Pettersson and Turkheimer (2010).
- **Structure**: An item by factor structure matrix of class “loadings”. This is just the loadings (pattern) matrix times the factor intercorrelation matrix.
- **fit**: How well does the factor model reproduce the correlation matrix. This is just $\frac{\sum_{ij}(r_{ij}^2 - r_{ij}^*^2)}{\sum_{ij}r_{ij}^2}$ (See VSS, ICLUST, and `principal` for this fit statistic.
- **fit.off**: how well are the off diagonal elements reproduced?
- **dof**: Degrees of Freedom for this model. This is the number of observed correlations minus the number of independent parameters. Let n=Number of items, nf = number of factors then 
  $$dof = n * (n - 1)/2 - n * nf + nf * (nf - 1)/2$$
- **objective**: Value of the function that is minimized by a maximum likelihood procedures. This is reported for comparison purposes and as a way to estimate chi square goodness of fit. The objective function is 
  $$f = \log(\text{trace}((FF' + U^2)^{-1}R) - \log((FF' + U^2)^{-1}R))) - n.\text{items.}$$
  When using MLE, this function is minimized. When using OLS (minres), although we are not minimizing this function directly, we can still calculate it in order to compare the solution to a MLE fit.
- **STATISTIC**: If the number of observations is specified or found, this is a chi square based upon the objective function, $f$ (see above). Using the formula from `factanal` (which seems to be Bartlett’s test):
  $$\chi^2 = (n.\text{obs} - 1 - (2 * p + 5)/6 - (2 * factors)/3) * f$$
- **PVAL**: If n.obs > 0, then what is the probability of observing a chisquare this large or larger?
- **Phi**: If oblique rotations (using oblimin from the GPArotation package or promax) are requested, what is the interfactor correlation.
- **communality.iterations**: The history of the communality estimates (For principal axis only.) Probably only useful for teaching what happens in the process of iterative fitting.
- **residual**: The matrix of residual correlations after the factor model is applied. To display it conveniently, use the `residuals` command.
- **chi**: When normal theory fails (e.g., in the case of non-positive definite matrices), it useful to examine the empirically derived $\chi^2$ based upon the sum of the squared residuals * N. This will differ slightly from the MLE estimate which is based upon the fitting function rather than the actual residuals.
| **rms** | This is the sum of the squared (off diagonal residuals) divided by the degrees of freedom. Comparable to an RMSEA which, because it is based upon $\chi^2$, requires the number of observations to be specified. The rms is an empirical value while the RMSEA is based upon normal theory and the non-central $\chi^2$ distribution. That is to say, if the residuals are particularly non-normal, the rms value and the associated $\chi^2$ and RMSEA can differ substantially. |
| **crms** | rms adjusted for degrees of freedom |
| **RMSEA** | The Root Mean Square Error of Approximation is based upon the non-central $\chi^2$ distribution and the $\chi^2$ estimate found from the MLE fitting function. With normal theory data, this is fine. But when the residuals are not distributed according to a noncentral $\chi^2$, this can give very strange values. (And thus the confidence intervals can not be calculated.) The RMSEA is a conventional index of goodness (badness) of fit but it is also useful to examine the actual rms values. |
| **TLI** | The Tucker Lewis Index of factoring reliability which is also known as the non-normed fit index. |
| **BIC** | Based upon $\chi^2$ with the assumption of normal theory and using the $\chi^2$ found using the objective function defined above. This is just $\chi^2 - 2df$. |
| **eBIC** | When normal theory fails (e.g., in the case of non-positive definite matrices), it useful to examine the empirically derived eBIC based upon the empirical $\chi^2 - 2 df$. |
| **R2** | The multiple R square between the factors and factor score estimates, if they were to be found. (From Grice, 2001). Derived from R2 is is the minimum correlation between any two factor estimates = $2R^2-1$. |
| **r.scores** | The correlations of the factor score estimates using the specified model, if they were to be found. Comparing these correlations with that of the scores themselves will show, if an alternative estimate of factor scores is used (e.g., the tenBerge method), the problem of factor indeterminacy. For these correlations will not necessarily be the same. |
| **weights** | The beta weights to find the factor score estimates. These are also used by the predict.psych function to find predicted factor scores for new cases. |
| **scores** | The factor scores as requested. Note that these scores reflect the choice of the way scores should be estimated (see scores in the input). That is, simple regression ("Thurstone"), correlation preserving ("tenBerge") as well as "Anderson" and "Bartlett" using the appropriate algorithms (see factor.scores). The correlation between factor score estimates (r.scores) is based upon using the regression/Thurstone approach. The actual correlation between scores will reflect the rotation algorithm chosen and may be found by correlating those scores. |
| **valid** | The validity coefficient of course coded (unit weighted) factor score estimates (From Grice, 2001) |
| **score.cor** | The correlation matrix of course coded (unit weighted) factor score estimates, if they were to be found, based upon the loadings matrix rather than the weights matrix. |
| **rot.mat** | The rotation matrix as returned from GPArotation. |

**Note**

Thanks to Erich Studerus for some very helpful suggestions about various rotation and factor scoring algorithms, and to Gumundur Arnkelsson for suggestions about factor scores for singular matrices.
The fac function is the original fa function which is now called by fa repeatedly to get confidence intervals.

SPSS will sometimes use a Kaiser normalization before rotating. This will lead to different solutions than reported here. To get the Kaiser normalized loadings, use kaiser.

The communality for a variable is the amount of variance accounted for by all of the factors. That is to say, for orthogonal factors, it is the sum of the squared factor loadings (rowwise). The communality is insensitive to rotation. However, if an oblique solution is found, then the communality is not the sum of squared pattern coefficients. In both cases (oblique or orthogonal) the communality is the diagonal of the reproduced correlation matrix where \( R = \Phi P' \), where \( P \) is the pattern matrix and \( \Phi \) is the factor intercorrelation matrix. This is the same, of course, of course to multiplying the pattern by the structure: \( R = PS' \). Similarly, the eigen values are the diagonal of the product \( \Phi P' \).

A frequently asked question is why are the factor names of the rotated solution not in ascending order? That is, for example, if factoring the 25 items of the bfi, the factor names are MR2 MR3 MR5 MR1 MR4, rather than the seemingly more logical "MR1" "MR2" "MR3" "MR4" "MR5". This is for pedagogical reasons, in that factors as extracted are orthogonal and are in order of amount of variance accounted for. But when rotated (orthogonally) or transformed (obliquely) the simple structure solution does not preserve that order. The factor names are, of course, arbitrary, and are kept with the original names to show the effect of rotation/transformation. To give them names associated with their ordinal position, simply paste("F", 1:nf, sep="") where nf is the number of factors. See the last example.

Correction to documentation: as of September, 2014, the oblique.scores option is correctly explained. (It had been backwards.) The default (oblique.scores=FALSE) finds scores based upon the Structure matrix, while oblique.scores=TRUE finds them based upon the pattern matrix. The latter case matches factanal. This error was detected by Mark Seeto.

#none, you should see fa
#using the Harman 24 mental tests, compare a principal factor with a principal components solution

---

fa.random

A first approximation to Random Effects Exploratory Factor Analysis

Description

Inspired, in part, by the wprifm function in the profileR package, fa.random removes between subject differences in mean level and then does a normal exploratory factor analysis of the ipsatized data. Functionally, this removes a general factor of the data before factoring. To prevent non-positive definiteness of the residual data matrix, a very small amount of random noise is added to each variable. This is just a call to fa after removing the between subjects effect. Read the help file for fa for a detailed explanation of all of the input parameters and the output objects.

Usage

fa.random(data, nfactors = 1, fix = TRUE, n.obs = NA, n.iter = 1, rotate = "oblimin", scores = "regression", residuals = FALSE, SMC = TRUE, covar = FALSE, missing = FALSE, impute = "median", min.err = 0.001, max.iter = 50, symmetric = TRUE, warnings = TRUE, fm = "minres", alpha = 0.1, p = 0.05, oblique.scores = FALSE, np.obs = NULL, use = "pairwise", cor = "cor", weight = NULL, ...)

Arguments

data A raw data matrix (or data.frame)
nfactors Number of factors to extract, default is 1
fix If TRUE, then a small amount of random error is added to each observed variable
to keep the matrix positive semi-definite. If FALSE, then this is not done but
because the matrix is non-positive semi-definite it will need to be smoothed
when finding the scores and the various statistics.
n.obs Number of observations used to find the correlation matrix if using a correlation
matrix. Used for finding the goodness of fit statistics. Must be specified if using
a correlaton matrix and finding confidence intervals. Ignored.
np.obs The pairwise number of observations. Used if using a correlation matrix and
asking for a minchi solution.
rotate "none", "varimax", "quartimax", "bentlerT", "equamax", "varimin", "geominT"
and "bifactor" are orthogonal rotations. "Promax", "promax", "oblimin", "simplicax","bentlerQ", "geominQ" and "biquartimin" and "cluster" are possible
oblique transformations of the solution. The default is to do a oblimin trans-
formation, although versions prior to 2009 defaulted to varimax. SPSS seems to
do a Kaiser normalization before doing Promax, this is done here by the call to
"promax" which does the normalization before calling Promax in GPArotation.
n.iter Number of bootstrap interations to do in fa or fa.poly
residuals Should the residual matrix be shown
scores the default="regression" finds factor scores using regression. Alternatives for
estimating factor scores include simple regression ("Thurstone"), correlaton pre-
serving ("tenBerge") as well as "Anderson" and "Bartlett" using the appropriate
algorithms ( factor.scores). Although scores="tenBerge" is probably preferred for most solutions, it will lead to problems with some improper corre-
lation matrices.
SMC Use squared multiple correlations (SMC=TRUE) or use 1 as initial communality
estimate. Try using 1 if imaginary eigen values are reported. If SMC is a vector
of length the number of variables, then these values are used as starting values
in the case of fm=’pa’.
covar if covar is TRUE, factor the covariance matrix, otherwise factor the correlation
matrix
missing if scores are TRUE, and missing=TRUE, then impute missing values using either
the median or the mean
impute "median" or "mean" values are used to replace missing values
min.err Iterate until the change in communalities is less than min.err
max.iter Maximum number of iterations for convergence
symmetric symmetric=TRUE forces symmetry by just looking at the lower off diagonal
values
warnings warnings=TRUE => warn if number of factors is too many
fm Factoring method fm="minres" will do a minimum residual as will fm="uls".
Both of these use a first derivative. fm="ols" differs very slightly from "min-
res" in that it minimizes the entire residual matrix using an OLS procedure but
uses the empirical first derivative. This will be slower. fm="wls" will do a
weighted least squares (WLS) solution, fm="gls" does a generalized weighted
least squares (GLS), fm="pa" will do the principal factor solution, fm="ml" will
do a maximum likelihood factor analysis. fm="minchi" will minimize the sample size weighted chi square when treating pairwise correlations with different number of subjects per pair. fm="minrank" will do a minimum rank factor analysis. "old.min" will do minimal residual the way it was done prior to April, 2017 (see discussion below).

**alpha**
alpha level for the confidence intervals for RMSEA

**p**
if doing iterations to find confidence intervals, what probability values should be found for the confidence intervals

**oblique.scores**
When factor scores are found, should they be based on the structure matrix (default) or the pattern matrix (oblique.scores=TRUE).

**weight**
If not NULL, a vector of length n.obs that contains weights for each observation. The NULL case is equivalent to all cases being weighted 1.

**use**
How to treat missing data, use="pairwise" is the default. See cor for other options.

**cor**
How to find the correlations: "cor" is Pearson", "cov" is covariance, "tet" is tetrachoric, "poly" is polychoric, "mixed" uses mixed cor for a mixture of tetrachorics, polychorics, Pearsons, biserials, and polyserials, Yuleb is Yulebonett, Yuleq and YuleY are the obvious Yule coefficients as appropriate

... additional parameters, specifically, keys may be passed if using the target rotation, or delta if using geominQ, or whether to normalize if using Varimax

**Details**
This function is inspired by the wprifm function in the profileR package and the citation there to a paper by Davison, Kim and Close (2009). The basic logic is to extract a means vector from each subject and then to analyze the resulting ipsatized data matrix. This can be seen as removing acquiescence in the case of personality items, or the general factor, in the case of ability items. Factors composed of items that are all keyed the same way (e.g., Neuroticism in the bfi data set) will be most affected by this technique.

The output is identical to the normal fa output with the addition of two objects: subject and within.r. The subject object is just the vector of the mean score for each subject on all the items. within.r is just the correlation of each item with those scores.

**Value**

**subject**
A vector of the mean score on all items for each subject

**within.r**
The correlation of each item with the subject vector

**values**
Eigen values of the common factor solution

**e.values**
Eigen values of the original matrix

**communality**
Communality estimates for each item. These are merely the sum of squared factor loadings for that item.

**communalities**
If using minrank factor analysis, these are the communalities reflecting the total amount of common variance. They will exceed the communality (above) which is the model estimated common variance.

**rotation**
which rotation was requested?

**n.obs**
number of observations specified or found

**loadings**
An item by factor (pattern) loading matrix of class “loadings” Suitable for use in other programs (e.g., GPA rotation or factor2cluster. To show these by sorted order, use print.psych with sort=TRUE
complexity
Hoffman’s index of complexity for each item. This is just \( \frac{(\sum a_i^2)^2}{\sum a_i^4} \) where \( a_i \) is the factor loading on the \( i \)th factor. From Hofmann (1978), MBR. See also Pettersson and Turkheimer (2010).

Structure
An item by factor structure matrix of class “loadings”. This is just the loadings (pattern) matrix times the factor intercorrelation matrix.

fit
How well does the factor model reproduce the correlation matrix. This is just \( \frac{\sum r^2_{ij} - \sum r^*_{ij}^2}{\sum r^2_{ij}} \) (See VSS, ICLUST, and principal for this fit statistic.

fit.off
how well are the off diagonal elements reproduced?

dof
Degrees of Freedom for this model. This is the number of observed correlations minus the number of independent parameters. Let \( n \) = Number of items, \( nf \) = number of factors then
\[
dof = n \ast (n - 1)/2 - n \ast nf + nf \ast (nf - 1)/2
\]

objective
Value of the function that is minimized by a maximum likelihood procedures. This is reported for comparison purposes and as a way to estimate chi square goodness of fit. The objective function is
\[
f = \log(\text{trace}((FF^T + U^2)^{-1}R) - \log(|(FF^T + U^2)^{-1}R|) - n.\text{items})
\]
When using MLE, this function is minimized. When using OLS (minres), although we are not minimizing this function directly, we can still calculate it in order to compare the solution to a MLE fit.

STATISTIC
If the number of observations is specified or found, this is a chi square based upon the objective function, \( f \) (see above). Using the formula from factanal (which seems to be Bartlett’s test):
\[
\chi^2 = (n.\text{obs} - 1 - (2 \ast p + 5)/6 - (2 \ast \text{factors}))/3 \ast f
\]

PVAL
If \( n.\text{obs} > 0 \), then what is the probability of observing a chisquare this large or larger?

Phi
If oblique rotations (e.g., using oblimin from the GPArotation package or promax) are requested, what is the interfactor correlation?

communality.iterations
The history of the communality estimates (For principal axis only.) Probably only useful for teaching what happens in the process of iterative fitting.

residual
The matrix of residual correlations after the factor model is applied. To display it conveniently, use the residuals command.

chi
When normal theory fails (e.g., in the case of non-positive definite matrices), it useful to examine the empirically derived \( \chi^2 \) based upon the sum of the squared residuals \( * N \). This will differ slightly from the MLE estimate which is based upon the fitting function rather than the actual residuals.

rms
This is the sum of the squared (off diagonal residuals) divided by the degrees of freedom. Comparable to an RMSEA which, because it is based upon \( \chi^2 \), requires the number of observations to be specified. The rms is an empirical value while the RMSEA is based upon normal theory and the non-central \( \chi^2 \) distribution. That is to say, if the residuals are particularly non-normal, the rms value and the associated \( \chi^2 \) and RMSEA can differ substantially.

crms
rms adjusted for degrees of freedom

RMSEA
The Root Mean Square Error of Approximation is based upon the non-central \( \chi^2 \) distribution and the \( \chi^2 \) estimate found from the MLE fitting function. With normal theory data, this is fine. But when the residuals are not distributed according to a noncentral \( \chi^2 \), this can give very strange values. (And thus the
confidence intervals can not be calculated.) The RMSEA is a conventional index of goodness (badness) of fit but it is also useful to examine the actual rms values.

TLI The Tucker Lewis Index of factoring reliability which is also known as the non-normed fit index.

BIC Based upon $\chi^2$ with the assumption of normal theory and using the $\chi^2$ found using the objective function defined above. This is just $\chi^2 - 2df$

eBIC When normal theory fails (e.g., in the case of non-positive definite matrices), it useful to examine the empirically derived eBIC based upon the empirical $\chi^2 - 2 df$.

R2 The multiple R square between the factors and factor score estimates, if they were to be found. (From Grice, 2001). Derived from R2 is is the minimum correlation between any two factor estimates = 2R2-1.

r.scores The correlations of the factor score estimates using the specified model, if they were to be found. Comparing these correlations with that of the scores themselves will show, if an alternative estimate of factor scores is used (e.g., the tenBerge method), the problem of factor indeterminacy. For these correlations will not necessarily be the same.

weights The beta weights to find the factor score estimates. These are also used by the predict.psych function to find predicted factor scores for new cases. These weights will depend upon the scoring method requested.

scores The factor scores as requested. Note that these scores reflect the choice of the way scores should be estimated (see scores in the input). That is, simple regression ("Thurstone"), correlataton preserving ("tenBerge") as well as "Anderson" and "Bartlett" using the appropriate algorithms (see factor.scores). The correlation between factor score estimates (r.scores) is based upon using the regression/Thurstone approach. The actual correlation between scores will reflect the rotation algorithm chosen and may be found by correlating those scores. Although the scores are found by multiplyng the standarized data by the weights matrix, this will not result in standard scores if using regression.

valid The validity coeffiecient of course coded (unit weighted) factor score estimates (From Grice, 2001)

score.cor The correlation matrix of course coded (unit weighted) factor score estimates, if they were to be found, based upon the loadings matrix rather than the weights matrix.

rot.mat The rotation matrix as returned from GPArotation.

Note

An interesting, but not necessarily good, idea. To see what this does if there is a general factor, consider the unrotated solutions to the ability data set. In particular, compare the first factor loading with its congruence to the ipsatized solution means vector correlated with the items (the within.r object).

fa.sort

Sort factor analysis or principal components analysis loadings

Description

Although the print.psych function will sort factor analysis loadings, sometimes it is useful to do this outside of the print function. fa.sort takes the output from the fa or principal functions and sorts the loadings for each factor. Items are located in terms of their greatest loading. The new order is returned as an element in the fa list. fa.organize allows for the columns or rows to be reorganized.

Usage

fa.sort(fa.results,polar=FALSE)
fa.organize(fa.results,o=NULL,i=NULL,cn=NULL,echelon=TRUE,flip=TRUE)

Arguments

fa.results The output from a factor analysis or principal components analysis using fa or principal. Can also just be a matrix of loadings.
polar Sort by polar coordinates of first two factors (FALSE)
o The order in which to order the factors
i The order in which to order the items
cn new factor names
echelon Organize the factors so that they are in echelon form (variable 1 .. n on factor 1, n+1 ...n=k on factor 2, etc.)
flip Flip factor loadings such that the colMean is positive.

Details

The fa.results$loadings are replaced with sorted loadings.
fa.organize takes a factor analysis or components output and reorganizes the factors in the o order. Items are organized in the i order. This is useful when comparing alternative factor solutions.
The flip option works only for the case of matrix input, not for full fa objects. Use the reflect function.
faCor

Value

A sorted factor analysis, principal components analysis, or omega loadings matrix. These sorted values are used internally by the various diagram functions. The values returned are the same as fa, except in sorted order. In addition, the order is returned as an additional element in the fa list.

faCor

Correlations between two factor analysis solutions

Description

Given two factor analysis or pca solutions to a data matrix or correlation, what are the similarities between the two solutions. This may be found by factor correlations as well as factor congruences. Factor correlations are found by the matrix product of the factor weights and the correlation matrix and are estimates of what the factor score correlations would be. Factor congruence (aka Tucker or Burt coefficient) is the cosine of the vectors of factor loadings.

Usage

faCor(r, nfactors = c(1, 1), fm = c("minres", "minres"), rotate = c("oblimin", "oblimin"), scores = c("tenBerge", "tenBerge"), adjust = c(TRUE, TRUE), use = "pairwise", cor = "cor", weight = NULL, correct = 0.5, Target=list(NULL,NULL))

Arguments

r A correlation matrix or a data matrix suitable for factoring
nfactors Number of factors in each solution to extract
fm Factor method. The default is 'minres' factoring. To compare with pca solutions, can also be (fm ="pca")
rotate What type of rotations to apply. The default for factors is oblimin, for pca is varimax.
scores What factor scoring algorithm should be used. Defaults to tenBerge for both cases.
adjust Should the factor intercorrelations be corrected by the lack of factor determinacy (i.e. divide by the square root of the factor R2)
faCor

**use**
How to treat missing data. Use="pairwise" finds pairwise complete correlations.

**cor**
What kind of correlation to find. The default is Pearson.

**weight**
Should cases be weighted? Default, no.

**correct**
If finding tetrachoric or polychoric correlations, what correction should be applied to empty cells (defaults to .5)

**Target**
If doing target rotations (e.g., TargetQ or TargetT), then the Target must be specified. If TargetT, this may be a matrix, if TargetQ, this must be a list. (Strange property of GPArotation.)

**Details**

The factor correlations are found using the approach discussed by Gorsuch (1983) and uses the weights matrices found by $w = S R^{-1}$ and $r = w' R w$ where $S$ is the structure matrix and is $s = F\Phi$. The resulting correlations may be adjusted for the factor score variances (the diagonal of $r$) (the default).

For factor loading vectors of $F_1$ and $F_2$ the measure of factor congruence, phi, is

$$\phi = \frac{\sum F_1 F_2}{\sqrt{\sum F_1^2} \sum F_2^2}$$

and is also found in factor.congruence.

For comparisons of factor solutions from 1 to n, use bassAckward. This function just compares two solutions from the same correlation/data matrix. factor.congruence can be used to compare any two sets of factor loadings.

Note that alternative ways of finding weights (e.g., regression, Bartlett, tenBerge) will produce somewhat different results. tenBerge produces weights that maintain the factor correlations in the factor scores.

**Value**

- **Call**
The function call
- **r**
The factor intercorrelations
- **congruence**
The Burt/Tucker coefficient of congruence
- **f1**
The first factor analysis
- **f2**
The second factor analysis

**Note**

Useful for comparing factor solutions from the same data. Will not work for different data sets

factor.congruence

Coefficient of factor congruence

Description

Given two sets of factor loadings, report their degree of congruence (vector cosine). Although first reported by Burt (1948), this is frequently known as the Tucker index of factor congruence.

Usage

factor.congruence(x, y=NULL,digits=2,use=NULL,structure=FALSE)
fa.congruence(x, y=NULL,digits=2,use=NULL,structure=FALSE)

Arguments

x A matrix of factor loadings or a list of matrices of factor loadings
y A second matrix of factor loadings (if x is a list, then y may be empty)
digits Round off to digits
use If NULL, then no loading matrices may contain missing values. If use="complete" then variables with any missing loadings are dropped (with a warning)
structure If TRUE, find the factor congruences based upon the Structure matrix (if available), otherwise based upon the pattern matrix.
Details

Find the coefficient of factor congruence between two sets of factor loadings.

Factor congruences are the cosines of pairs of vectors defined by the loadings matrix and based at the origin. Thus, for loadings that differ only by a scaler (e.g. the size of the eigen value), the factor congruences will be 1.

For factor loading vectors of $F_1$ and $F_2$ the measure of factor congruence, $\phi$, is

$$\phi = \frac{\sum F_1 F_2}{\sqrt{\sum (F_1^2) \sum (F_2^2)}}$$

It is an interesting exercise to compare factor congruences with the correlations of factor loadings. Factor congruences are based upon the raw cross products, while correlations are based upon centered cross products. That is, correlations of factor loadings are cosines of the vectors based at the mean loading for each factor.

$$\phi = \frac{\sum (F_1 - a)(F_2 - b)}{\sqrt{\sum ((F_1 - a)^2) \sum ((F_2 - b)^2)}}.$$

For congruence coefficients, $a = b = 0$. For correlations $a=\text{mean } F_1$, $b=\text{mean } F_2$.

Input may either be matrices or factor analysis or principal components analysis output (which includes a loadings object), or a mixture of the two.

To compare more than two solutions, x may be a list of matrices, all of which will be compared.

Normally, all factor loading matrices should be complete (have no missing loadings). In the case where some loadings are missing, if the use option is specified, then variables with missing loadings are dropped.

Value

A matrix of factor congruences.

factor.fit

How well does the factor model fit a correlation matrix. Part of the VSS package

Description

The basic factor or principal components model is that a correlation or covariance matrix may be reproduced by the product of a factor loading matrix times its transpose: \( FF' \) or \( PP' \). One simple index of fit is the \( 1 - \text{sum squared residuals/sum squared original correlations} \). This fit index is used by VSS, ICLUST, etc.

Usage

factor.fit(r, f)

Arguments

r
a correlation matrix

f
A factor matrix of loadings.

Details

There are probably as many fit indices as there are psychometricians. This fit is a plausible estimate of the amount of reduction in a correlation matrix given a factor model. Note that it is sensitive to the size of the original correlations. That is, if the residuals are small but the original correlations are small, that is a bad fit.

Let

\[
R^* = R - FF'
\]

\[
\text{fit} = 1 - \frac{\sum(R^*^2)}{\sum(R^2)}
\]

The sums are taken for the off diagonal elements.

Value

fit

Author(s)

William Revelle

```r
## Not run:
#compare the fit of 4 to 3 factors for the Harman 24 variables
fa4 <- factanal(x,4,covmat=Harman74.cor$cov)
round(factor.fit(Harman74.cor$cov,fa4$loading),2)
#[1] 0.9
fa3 <- factanal(x,3,covmat=Harman74.cor$cov)
round(factor.fit(Harman74.cor$cov,fa3$loading),2)
#[1] 0.88

## End(Not run)
```

factor.model

Find $R = FF' + U2$ is the basic factor model

Description

The basic factor or principal components model is that a correlation or covariance matrix may be reproduced by the product of a factor loading matrix times its transpose. Find this reproduced matrix. Used by `factor.fit`, `VSS`, `ICLUST`, etc.

Usage

```r
factor.model(f,Phi=NULL,U2=TRUE)
```

Arguments

- `f` A matrix of loadings.
- `Phi` A matrix of factor correlations
- `U2` Should the diagonal be model by $ff'$ ($U2 = TRUE$) or replaced with 1's ($U2 = FALSE$)

Value

A correlation or covariance matrix.

Author(s)

<revelle@northwestern.edu>

https://personality-project.org/revelle.html

factor.residuals

Examples

```r
f2 <- matrix(c(.9,.8,.7,rep(0,6),.6,.7,.8,ncol=2)
mod <- factor.model(f2)
round(mod,2)
```

```r
factor.residuals  \quad R^* = R - F'F'
```

Description

The basic factor or principal components model is that a correlation or covariance matrix may be reproduced by the product of a factor loading matrix times its transpose. Find the residuals of the original minus the reproduced matrix. Used by factor.fit, VSS, ICLUST, etc.

Usage

```r
factor.residuals(r, f)
```

Arguments

- `r`  
  A correlation matrix
- `f`  
  A factor model matrix or a list of class loadings

Details

The basic factor equation is \( R \approx F_kk F_k' + U^2 \). Residuals are just \( R^* = R - F'F \). The residuals should be (but in practice probably rarely are) examined to understand the adequacy of the factor analysis. When doing Factor analysis or Principal Components analysis, one usually continues to extract factors/components until the residuals do not differ from those expected from a random matrix.

Value

`rstar` is the residual correlation matrix.

Examples

```r
fa2 <- fa(Harman74.cor$cov,2,rotate=TRUE)
fa2resid <- factor.residuals(Harman74.cor$cov,fa2)
fa2resid[1:4,1:4]  #residuals with two factors extracted
fa4 <- fa(Harman74.cor$cov,4,rotate=TRUE)
fa4resid <- factor.residuals(Harman74.cor$cov,fa4)
fa4resid[1:4,1:4]  #residuals with 4 factors extracted
```
factor.rotate "Hand" rotate a factor loading matrix

Description

Given a factor or components matrix, it is sometimes useful to do arbitrary rotations of particular pairs of variables. This supplements the much more powerful rotation package GPArotation and is meant for specific requirements to do unusual rotations.

Usage

factor.rotate(f, angle, col1=1, col2=2, plot=FALSE, ...)

Arguments

f original loading matrix or a data frame (can be output from a factor analysis function
angle angle (in degrees!) to rotate
col1 column in factor matrix defining the first variable
col2 column in factor matrix defining the second variable
plot plot the original (unrotated) and rotated factors
... parameters to pass to fa.plot

Details

Partly meant as a demonstration of how rotation works, factor.rotate is useful for those cases that require specific rotations that are not available in more advanced packages such as GPArotation. If the plot option is set to TRUE, then the original axes are shown as dashed lines.

The rotation is in degrees counter clockwise.

Value

the resulting rotated matrix of loadings.

Note

For a complete rotation package, see GPArotation

factor.scores

Examples

#using the Harman 24 mental tests, rotate the 2nd and 3rd factors 45 degrees
f4 <- fa(Harman74.cor$cov, 4, rotate = "TRUE")
f4r45 <- factor.rotate(f4, 45, 2, 3)
f4r90 <- factor.rotate(f4r45, 45, 2, 3)
print(factor.congruence(f4, f4r45), digits = 3)  # poor congruence with original
print(factor.congruence(f4, f4r90), digits = 3)  # factor 2 and 3 have been exchanged and 3 flipped

#a graphic example
data(Harman23.cor)
f2 <- fa(Harman23.cor$cov, 2, rotate = "none")
op <- par(mfrow = c(1, 2))
cluster.plot(f2, xlim = c(-1, 1), ylim = c(-1, 1), title = "Unrotated")
f2r <- factor.rotate(f2, -33, plot = TRUE, xlim = c(-1, 1), ylim = c(-1, 1), title = "rotated -33 degrees")
op <- par(mfrow = c(1, 1))

factor.scores

Various ways to estimate factor scores for the factor analysis model

Description

A fundamental problem with factor analysis is that although the model is defined at the structural level, it is indeterminate at the data level. This problem of factor indeterminancy leads to alternative ways of estimating factor scores, none of which is ideal. Following Grice (2001) four different methods are available here.

Usage

factor.scores(x, f, Phi = NULL, method = c("Thurstone", "tenBerge", "Anderson", "Bartlett", "Harman","components"), rho = NULL, impute = "none")

Arguments

x Either a matrix of data if scores are to be found, or a correlation matrix if just the factor weights are to be found.
f The output from the fa or irt.fa functions, or a factor loading matrix.
Phi If a pattern matrix is provided, then what were the factor intercorrelations. Does not need to be specified if f is the output from the fa or irt.fa functions.
method Which of four factor score estimation procedures should be used. Defaults to "Thurstone" or regression based weights. See details below for the other four methods.
rho If x is a set of data and rho is specified, then find scores based upon the fa results and the correlations reported in rho. Used when scoring fa.poly results.
impute By default, only complete cases are scored. But, missing data can be imputed using "median" or "mean". The number of missing by subject is reported.
Details

Although the factor analysis model is defined at the structural level, it is undefined at the data level. This is a well known but little discussed problem with factor analysis.

Factor scores represent estimates of common part of the variables and should not be thought of as identical to the factors themselves. If a factor is thought of as a chop stick stuck into the center of an ice cream cone and factor score estimates are represented by straws anywhere along the edge of the cone the problem of factor indeterminacy becomes clear, for depending on the shape of the cone, two straws can be negatively correlated with each other. (The imagery is taken from Niels Waller, adapted from Stanley Mulaik). In a very clear discussion of the problem of factor score indeterminacy, Grice (2001) reviews several alternative ways of estimating factor scores and considers weighting schemes that will produce uncorrelated factor score estimates as well as the effect of using course coded (unit weighted) factor weights.

factor.scores uses four different ways of estimate factor scores. In all cases, the factor score estimates are based upon the data matrix, X, times a weighting matrix, W, which weights the observed variables.

For polytomous or dichotomous data, factor scores can be estimated using Item Response Theory techniques (e.g., using link{irt.fa} and then link{scoreIrt}). Such scores are still just factor score estimates, for the IRT model is a latent variable model equivalent to factor analysis.

- method="Thurstone" finds the regression based weights: \( W = R^{-1}F \) where R is the correlation matrix and F is the factor loading matrix.
- method="tenBerge" finds weights such that the correlation between factors for an oblique solution is preserved. Note that formula 8 in Grice has a typo in the formula for C and should be: \( L = F\Phi^{1/2} \) \( C = R^{1/2}L(L'\Phi^{-1/2}L-1)^{-1/2} \) \( W = R^{1/2}(L'\Phi^{-1/2}L)^{-1/2} \)
- method="Anderson" finds weights such that the factor scores will be uncorrelated: \( W = U^{-2}F(F'U^{-2}RU^{-2}F)^{-1/2} \) where U is the diagonal matrix of uniquenesses. The Anderson method works for orthogonal factors only, while the tenBerge method works for orthogonal or oblique solutions.
- method = "Bartlett" finds weights given \( W = U^{-2}F(F'U^{-2}F)^{-1} \)
- method="Harman" finds weights based upon so-called "idealized" variables: \( W = F(t(F)F)^{-1} \).
- method="components" uses weights that are just component loadings.

Value

- scores (the factor scores if the raw data is given)
- weights (the factor weights)
- r.scores (The correlations of the factor score estimates.)
- missing A vector of the number of missing observations per subject

factor.stats

Find various goodness of fit statistics for factor analysis and principal components

Description

Chi square and other goodness of fit statistics are found based upon the fit of a factor or components model to a correlation matrix. Although these statistics are normally associated with a maximum likelihood solution, they can be found for minimal residual (OLS), principal axis, or principal component solutions as well. Primarily called from within these functions, factor.stats can be used by itself. Measures of factorial adequacy and validity follow the paper by Grice, 2001.

Usage

fa.stats(r=NA,f,phi=NA,n.obs=NA,np.obs=NA, alpha=.05,fm=FALSE)
factor.stats(r=NA,f,phi=NA,n.obs=NA,np.obs=NA, alpha=.1,fm=FALSE)

Arguments

r A correlation matrix or a data frame of raw data
f A factor analysis loadings matrix or the output from a factor or principal components analysis. In which case the r matrix need not be specified.
phi A factor intercorrelation matrix if the factor solution was oblique.
n.obs The number of observations for the correlation matrix. If not specified, and a correlation matrix is used, chi square will not be reported. Not needed if the input is a data matrix.
np.obs The pairwise number of subjects for each pair in the correlation matrix. This is used for finding observed chi square.
alpha alpha level of confidence intervals for RMSEA (twice the confidence at each tail)
fm flag if components are being given statistics
factor.stats

Details

Combines the goodness of fit tests used in \texttt{fa} and \texttt{principal} into one function. If the matrix is singular, will smooth the correlation matrix before finding the fit functions. Now will find the RMSEA (root mean square error of approximation) and the alpha confidence intervals similar to a SEM function. Also reports the root mean square residual.

Chi square is found two ways. The first (\texttt{STATISTIC}) applies the goodness of fit test from Maximum Likelihood objective function (see below). This assumes multivariate normality. The second is the empirical chi square based upon the observed residual correlation matrix and the observed sample size for each correlation. This is found by summing the squared residual correlations time the sample size.

Value

- **fit**: How well does the factor model reproduce the correlation matrix. (See \texttt{VSS}, \texttt{ICLUST}, and \texttt{principal} for this fit statistic.
- **fit.off**: how well are the off diagonal elements reproduced? This is just 1 - the relative magnitude of the squared off diagonal residuals to the squared off diagonal original values.
- **dof**: Degrees of Freedom for this model. This is the number of observed correlations minus the number of independent parameters. Let n=Number of items, nf = number of factors then 
  
  \[
  dof = n \times (n - 1)/2 - n \times nf + nf \times (nf - 1)/2
  \]
- **objective**: value of the function that is minimized by maximum likelihood procedures. This is reported for comparison purposes and as a way to estimate chi square goodness of fit. The objective function is 
  
  \[
  f = \log(\text{trace}((FF' + U^2)^{-1}\mathbf{R}) - \log(|(FF' + U^2)^{-1}\mathbf{R}|)) - n \times \text{items}.
  \]
- **STATISTIC**: If the number of observations is specified or found, this is a chi square based upon the objective function, f. Using the formula from \texttt{factanal}(which seems to be Bartlett’s test) :
  
  \[
  \chi^2 = (n \times \text{obs} - 1 - (2 \times p + 5)/6 - (2 \times \text{factors}/3)) \times f
  \]
  
  Note that this is different from the chi square reported by the \texttt{sem} package which seems to use 
  
  \[
  \chi^2 = (n \times \text{obs} - 1 - (2 \times p + 5)/6 - (2 \times \text{factors}/3)) \times f
  \]
- **PVAL**: If n.obs > 0, then what is the probability of observing a chisquare this large or larger?
- **Phi**: If oblique rotations (using oblimin from the GPArotation package or promax) are requested, what is the interfactor correlation.
- **R2**: The multiple R square between the factors and factor score estimates, if they were to be found. (From Grice, 2001)
- **r.scores**: The correlations of the factor score estimates, if they were to be found.
- **weights**: The beta weights to find the factor score estimates
- **valid**: The validity coefficient of course coded (unit weighted) factor score estimates (From Grice, 2001)
- **score.cor**: The correlation matrix of course coded (unit weighted) factor score estimates, if they were to be found, based upon the loadings matrix.
- **RMSEA**: The Root Mean Square Error of Approximation and the alpha confidence intervals. Based upon the chi square non-centrality parameter. This is found as 
  
  \[
  \sqrt{f/dof - 1/(f - 1)}
  \]
The empirically found square root of the squared residuals. This does not require sample size to be specified nor does it make assumptions about normality. While the rms uses the number of correlations to find the average, the crms uses the number of degrees of freedom. Thus, there is a penalty for having too complex a model.

See Also

fa with fm="pa" for principal axis factor analysis, fa with fm="minres" for minimum residual factor analysis (default). factor.pa also does principal axis factor analysis, but is deprecated, as is factor.minres for minimum residual factor analysis. See principal for principal components.

Examples

v9 <- sim.hierarchical()
f3 <- fa(v9,3)
factor.stats(v9,f3,n.obs=500)
f3o <- fa(v9,3,fm="pa",rotate="Promax")
factor.stats(v9,f3o,n.obs=500)

Description

Given a factor or principal components loading matrix, assign each item to a cluster corresponding to the largest (signed) factor loading for that item. Essentially, this is a Very Simple Structure approach to cluster definition that corresponds to what most people actually do: highlight the largest loading for each item and ignore the rest.

Usage

factor2cluster(loads, cut = 0,aslist=FALSE)

Arguments

loads either a matrix of loadings, or the result of a factor analysis/principal components analysis with a loading component

cut Extract items with absolute loadings > cut

aslist if TRUE, Return a keys list, else return a keys matrix (old style)
Details

A factor/principal components analysis loading matrix is converted to a cluster (-1,0,1) definition matrix where each item is assigned to one and only one cluster. This is a fast way to extract items that will be unit weighted to form cluster composites. Use this function in combination with cluster.cor to find the correlations of these composite scores.

A typical use in the SAPA project is to form item composites by clustering or factoring (see ICLUST, principal), extract the clusters from these results (factor2cluster), and then form the composite correlation matrix using cluster.cor. The variables in this reduced matrix may then be used in multiple R procedures using mat.regress.

The input may be a matrix of item loadings, or the output from a factor analysis which includes a loadings matrix.

Value

a keys list (new style or a matrix of -1,0,1 cluster definitions for each item.

#matches the factanal example
f4 <- fa(Harman74.cor$cov,4,rotate="varimax")
factor2cluster(f4)

fisherz Transforms of r, d, and t including Fisher r to z and z to r and confidence intervals

Description

Convert a correlation to a z or t, or d, or chi or covariance matrix or z to r using the Fisher transformation or find the confidence intervals for a specified correlation. r2d converts a correlation to an effect size (Cohen’s d) and d2r converts a d into an r. g2r converts Hedge’s g to a correlation. t2r converts a t test to r, r2t converts a correlation to a t-test value. chi2r converts a chi square to r, r2chi converts it back. r2c and cor2cov convert a correlation matrix to a covariance matrix. d2t and t2d convert cohen’s d into a t and a t into a cohen d. See cohen.d for other conversions.
Usage

fisherz(rho)
fisherz2r(z)
r.con(rho,n,p=.95,twotailed=TRUE)
r2t(rho,n)
t2r(t,df)
g2r(g,df,n)
chi2r(chi2,n)
r2chi(rho,n)
r2c(rho,sigma)
cor2cov(rho,sigma)

Arguments

rho       a Pearson r
z         A Fisher z
n         Sample size for confidence intervals
df        degrees of freedom for t, or g
p         Confidence interval
twotailed Treat p as twotailed p
g         An effect size (Hedge’s g)
t         A student’s t value
chi2      A chi square
sigma     a vector of standard deviations to be used to convert a correlation matrix to a covariance matrix

Value

z         value corresponding to r (fisherz)
r         r corresponding to z (fisherz2r)
r.con     lower and upper p confidence intervals (r.con)
t         t with n-2 df (r2t)
r         r corresponding to effect size d or d corresponding to r.
r2c       r2c is the reverse of the cor2con function of base R. It just converts a correlation matrix to the corresponding covariance matrix given a vector of standard deviations.

Author(s)

Maintainer: William Revelle <revelle@northwestern.edu>
Examples

```r	n <- 30
r <- seq(0,.9,.1)
d <- r2d(r)
rc <- matrix(r.con(r,n),ncol=2)
t <- r*sqrt(n-2)/sqrt(1-r^2)
p <- (1-pt(t,n-2))*2
r1 <- t2r(t,(n-2))
r2 <- d2r(d)
chi <- r2chi(r,n)
r3 <- chi2r(chi,n)
r.rc <- data.frame(r=r,z=fisherz(r),lower=rc[,1],upper=rc[,2],
t=t,p=p,d=d,
                    chi2=chi,d2r=r2,t2r=r1,chi2r=r3)
round(r.rc,2)
```

Usage

fparse(expr)

Arguments

expr A legitimate expression in the form y ~ x1 , etc. (see details)

Details

The basic formula input given as DV1 + DV2 ~ IV1 + IV2 + (IV3) + I(IV4^2) - IV5 will be parsed to return 2 DVs (1 and 2), two normal IVs (1 and 2), a mediator (IV3) a quadratic (IV4) and a variable to be partialed (IV5). See the various examples in setCor and mediate.

Value

y A list of elements from the left side of the formula
x A list of elements from the right side of the formula
m A list of those elements of the formula included in ()
prod A list of elements separated by a * sign
ex A list of elements marked by I()

Author(s)

William Revelle
Examples

```r
fparse(DV ~ IV1 + IV2 * IV3 + (IV4) + I(IV5^2) )
#somewhat more complicated
fparse(DV1 + DV2 ~ IV1 + IV2 + IV3*IV4 + I(IV5^2) + I(IV6^2) + (IV7) + (IV8) - IV9)
```

Description

Garcia, Schmitt, Branscome, and Ellemers (2010) report data for 129 subjects on the effects of perceived sexism on anger and liking of women’s reactions to ingroup members who protest discrimination. This data set is also used as the ‘protest’ data set by Hayes (2013 and 2018). It is a useful example of mediation and moderation in regression. It may also be used as an example of plotting interactions.

Usage

```r
data("GSBE")
```

Format

A data frame with 129 observations on the following 6 variables.

- **protest**: 0 = no protest, 1 = Individual Protest, 2 = Collective Protest
- **sexism**: Means of an 8 item Modern Sexism Scale.
- **anger**: Anger towards the target of discrimination. “I feel angry towards Catherine”.
- **liking**: Mean rating of 6 liking ratings of the target.
- **respappr**: Mean of four items of appropriateness of the target’s response.
- **prot2**: A recoding of protest into two levels (to match Hayes, 2013).

Details

The reaction of women to women who protest discriminatory treatment was examined in an experiment reported by Garcia et al. (2010). 129 women were given a description of sex discrimination in the workplace (a male lawyer was promoted over a clearly more qualified female lawyer). Subjects then read that the target lawyer felt that the decision was unfair. Subjects were then randomly assigned to three conditions: Control (no protest), Individual Protest (“They are treating me unfairly”), or Collective Protest (“The firm is is treating women unfairly”).

Participants were then asked how much they liked the target (liking), how angry they were to the target (anger) and to evaluate the appropriateness of the target’s response (respappr).

Garcia et al (2010) report a number of interactions (moderation effects) as well as moderated-mediation effects.

This data set is used as an example in Hayes (2013) for moderated mediation. It is used here to show how to do moderation (interaction terms) in regression (see `setCor`), how to do moderated mediation (see `mediate`) and how draw interaction graphs (see help).
Source

The data were downloaded from the webpages of Andrew Hayes (https://www.afhayes.com/public/hayes2018data.zip) supporting the first and second edition of his book. The second edition includes 6 variables, the first, just four. The protest variable in 2018 has three levels, but just two in the 2013 source.

The data are used by kind permission of Donna M. Garcia, Michael T. Schmitt, Nyla R. Branscombe, and Naomi Ellemers.

---

geometric.mean

Find the geometric mean of a vector or columns of a data.frame.

Description

The geometric mean is the nth root of a products or e to the mean log of x. Useful for describing non-normal, i.e., geometric distributions.

Usage

geometric.mean(x, na.rm=TRUE)
Arguments

- x: a vector or data.frame
- na.rm: remove NA values before processing

Details

Useful for teaching how to write functions, also useful for showing the different ways of estimating central tendency.

Value

geometric mean(s) of x or x.df.

Note

Not particularly useful if there are elements that are <= 0.

Author(s)

William Revelle

harmonic.mean, mean

Examples

```r
x <- seq(1,5)
x2 <- x^2
x2[2] <- NA
X <- data.frame(x,x2)
geometric.mean(x)
geometric.mean(x2)
geometric.mean(X)
geometric.mean(X,na.rm=FALSE)
```

---

**glb.algebraic**

*Find the greatest lower bound to reliability.*

Description

The greatest lower bound solves the “educational testing problem”. That is, what is the reliability of a test? (See guttman for a discussion of the problem). Although there are many estimates of a test reliability (Guttman, 1945) most underestimate the true reliability of a test.

For a given covariance matrix of items, C, the function finds the greatest lower bound to reliability of the total score using the csdp function from the Rcsdp package.

Usage

```r
glb.algebraic(Cov, LoBounds = NULL, UpBounds = NULL)
```
Arguments

- **Cov**: A p x p covariance matrix. Positive definiteness is not checked.
- **LoBounds**: A vector \( l = (l_1, \ldots, l_p) \) of length p with lower bounds to the diagonal elements \( x_i \). The default \( l=(0, \ldots, 0) \) does not imply any constraint, because positive semidefiniteness of the matrix \( \tilde{C} + \text{Diag}(x) \) implies \( 0 \leq x_i \)
- **UpBounds**: A vector \( u = (u_1, \ldots, u_p) \) of length p with upper bounds to the diagonal elements \( x_i \). The default is \( u = v \).

Details

If \( C \) is a p x p covariance matrix, \( v = \text{diag}(C) \) its diagonal (i.e. the vector of variances \( v_i = c_{ii} \)), \( \tilde{C} = C - \text{Diag}(v) \) is the covariance matrix with 0s substituted in the diagonal and \( x = (x_1, \ldots, x_n) \) the educational testing problem is (see e.g., Al-Homidan 2008)

\[
\sum_{i=1}^{p} x_i \rightarrow \min
\]

\[
\text{s.t.} \hspace{1cm} \tilde{C} + \text{Diag}(x) \geq 0
\]

(i.e. positive semidefinite) and \( x_i \leq v_i, i = 1, \ldots, p \). This is the same as minimizing the trace of the symmetric matrix

\[
\tilde{C} + \text{diag}(x) = \begin{pmatrix}
    x_1 & c_{12} & \ldots & c_{1p} \\
    c_{12} & x_2 & \ldots & c_{2p} \\
    \vdots & \vdots & \ddots & \vdots \\
    c_{1p} & c_{2p} & \ldots & x_p
\end{pmatrix}
\]

s. t. \( \tilde{C} + \text{Diag}(x) \) is positive semidefinite and \( x_i \leq v_i \).

The greatest lower bound to reliability is

\[
\frac{\sum_{ij} c_{ij} + \sum_i x_i}{\sum_{ij} c_{ij}}
\]

Additionally, function `glb.algebraic` allows the user to change the upper bounds \( x_i \leq v_i \) to \( x_i \leq u_i \) and add lower bounds \( l_i \leq x_i \).

The greatest lower bound to reliability is applicable for tests with non-homogeneous items. It gives a sharp lower bound to the reliability of the total test score.

Caution: Though `glb.algebraic` gives exact lower bounds for exact covariance matrices, the estimates from empirical matrices may be strongly biased upwards for small and medium sample sizes. `glb.algebraic` is wrapper for a call to function `csdp` of package Rcsdp (see its documentation).

If `Cov` is the covariance matrix of subtests/items with known lower bounds, `rel`, to their reliabilities (e.g. Cronbach’s \( \alpha \)), `LoBounds` can be used to improve the lower bound to reliability by setting `LoBounds <- rel*diag(Cov)`.

Changing `UpBounds` can be used to relax constraints \( x_i \leq v_i \) or to fix \( x_i \)-values by setting `LoBounds[i] <- -z`; `UpBounds[i] <- z`. 
Value

<table>
<thead>
<tr>
<th>glb</th>
<th>The algebraic greatest lower bound</th>
</tr>
</thead>
<tbody>
<tr>
<td>solution</td>
<td>The vector x of the solution of the semidefinite program. These are the elements on the diagonal of C.</td>

Examples

```r
Cv<-matrix(c(215, 64, 33, 22,
            64, 97, 57, 25,
            33, 57,103, 36,
            22, 25, 36, 77),ncol=4)
Cv # covariance matrix of a test with 4 subtests
Cr<-cov2cor(Cv) # Correlation matrix of tests
if(!require(Rcsdp)) {print("Rcsdp must be installed to find the glb.algebraic")}) else {
glb.algebraic(Cv) # glb of total score
glb.algebraic(Cr) # glb of sum of standardized scores
```
```r
w <- c(1, 2, 2, 1)  # glb of weighted total score
glb.algebraic(diag(w) %*% Cv %*% diag(w))
alphas <- c(0.8, 0, 0, 0)  # Internal consistency of first test is known
glb.algebraic(Cv, LoBounds = alphas * diag(Cv))

# Fix all diagonal elements to 1 but the first:
lb <- glb.algebraic(Cr, LoBounds = c(0, 1, 1, 1), UpBounds = c(1, 1, 1, 1))
lb$solution[1]  # should be the same as the squared mult. corr.
smc(Cr)[1]
```

Description

Gleser, Cronbach and Rajaratnam (1965) discuss the estimation of variance components and their ratios as part of their introduction to generalizability theory. This is a adaptation of their "illustrative data for a completely matched G study" (Table 3). 12 patients are rated on 6 symptoms by two judges. Components of variance are derived from the ANOVA.

Usage

data(Gleser)

Format

A data frame with 12 observations on the following 12 variables. J item by judge:

- J11 a numeric vector
- J12 a numeric vector
- J21 a numeric vector
- J22 a numeric vector
- J31 a numeric vector
- J32 a numeric vector
- J41 a numeric vector
- J42 a numeric vector
- J51 a numeric vector
- J52 a numeric vector
- J61 a numeric vector
- J62 a numeric vector

Example data from Gleser, Cronbach and Rajaratnam (1965) to show basic principles of generalizability theory.
Details

Generalizability theory is the application of a components of variance approach to the analysis of reliability. Given a G study (generalizability) the components are estimated and then may be used in a D study (Decision). Different ratios are formed as appropriate for the particular D study.

Harman

Five data sets from Harman (1967). 9 cognitive variables from Holzinger and 8 emotional variables from Burt

Description

Five classic data sets reported by Harman (1967) are 9 psychological (cognitive) variables taken from Holzinger and 8 emotional variables taken from Burt. Two others are socioeconomic and political data sets. Additionally, 8 physical variables. All five of these are used for tests and demonstrations of various factoring algorithms.

Usage

data(Harman)
data(Harman.5)
data(Harman.political)
data(Harman.8)

Details

- Harman.Holzinger: 9 x 9 correlation matrix of ability tests, N = 696.
- Harman.Burt: a 8 x 8 correlation matrix of "emotional" items. N = 172
- Harman.5: 12 census tracts for 5 socioeconomic data (Harman p 14)
- Harman.political: p 166.
- Harman.8 8 physical measures

Harman.Holzinger. The nine psychological variables from Harman (1967, p 244) are taken from unpublished class notes of K.J. Holzinger with 696 participants. This is a subset of 12 tests with 4 factors. It is yet another nice example of a bifactor solution. Bentler (2007) uses this data set to discuss reliability analysis. The data show a clear bifactor structure and are a nice example of the various estimates of reliability included in the omega function. Should not be confused with the Holzinger or Holzinger.9 data sets in bifactor.

Harman.Burt. Eight "emotional" variables are taken from Harman (1967, p 164) who in turn adapted them from Burt (1939). They are said be from 172 normal children aged nine to twelve. As pointed out by Harman, this correlation matrix is singular and has squared multiple correlations > 1. Because of this problem, it is a nice test case for various factoring algorithms. (For instance, omega will issue warning messages for fm="minres" or fm="pa" but will fail for fm="ml".)
The Eight Physical Variables problem is taken from Harman (1976) and represents the correlations between eight physical variables for 305 girls. The two correlated clusters represent four measures of "lankiness" and then four measures of "stockiness". The original data were selected from 17 variables reported in an unpublished dissertation by Mullen (1939).

Variable 6 ("Bitrochanteric diameter") is the distance between the outer points of the hips.

The row names match the original Harman paper, the column names have been abbreviated.

The \texttt{fa} solution for principal axes (\texttt{fm="pa"}) matches the reported minres solution, as does the \texttt{fm="minres"}.

For those interested in teaching examples using various body measurements, see the body data set in the gclus package.

The Burt data set probably has a typo in the original correlation matrix. Changing the Sorrow-Tenderness correlation from .87 to .81 makes the correlation positive definite.

As pointed out by Jan DeLeeuw, the Burt data set is a subset of 8 variables from the original 11 reported by Burt in 1915. That matrix has the same problem. See \texttt{burt}.

Other example data sets that are useful demonstrations of factor analysis are the seven bifactor examples in \texttt{Bechtoldt} and the 24 ability measures in \texttt{Harman74.cor}

There are several other Harman examples in the psych package (i.e., \texttt{Harman.8}) as well as in the datasets and GPArotation packages. The Harman 24 mental tests problem is in the basic datasets package at \texttt{Harman74.cor}.

Other Harman data sets are 5 socioeconomic variables for 12 census tracts \texttt{Harman.5} used by John Loehlin as an example for EFA. Another one of the many Harman (1967) data sets is \texttt{Harman.political}. This contains 8 political variables taken over 147 election areas. The principal factor method with SMCs as communalities match those of table 8.18. The data are used by Dziubian and Shirkey as an example of the Kaiser-Meyer-Olkin test of factor adequacy.

\textbf{See Also}

See also the original \texttt{burt} data set, the \texttt{Harman.5} and \texttt{Harman.political} data sets.

\textbf{Examples}

```r
data(Harman)
cor.plot(Harman.Holzinger)
cor.plot(Harman.Burt)
smc(Harman.Burt) #note how this produces impossible results
f2 <- fa(Harman.8,2, rotate="none") #minres matches Harman and Jones
```
harmonic.mean

Find the harmonic mean of a vector, matrix, or columns of a data.frame

Description

The harmonic mean is merely the reciprocal of the arithmetic mean of the reciprocals.

Usage

harmonic.mean(x, na.rm=TRUE, zero=TRUE)

Arguments

x: a vector, matrix, or data.frame
na.rm: na.rm=TRUE remove NA values before processing
zero: If TRUE, then if there are any zeros, return 0, else, return the harmonic mean of the non-zero elements

Details

Included as an example for teaching about functions. As well as for a discussion of how to estimate central tendencies. Also used in statsBy to weight by the harmonic mean.

Values of 0 can be included (in which case the harmonic.mean = 0) or converted to NA according to the zero option.

Added the zero option, March, 2017.

Value

The harmonic mean(s)

Note

Included as a simple demonstration of how to write a function

Examples

x <- seq(1,5)
x2 <- x^2
x2[2] <- NA
y <- x - 1
X <- data.frame(x, x2, y)
harmonic.mean(x)
harmonic.mean(x2)
harmonic.mean(X)
harmonic.mean(X, na.rm=FALSE)
harmonic.mean(X, zero=FALSE)
headTail

Combine calls to \texttt{head} and \texttt{tail}

\textbf{Description}

A quick way to show the first and last \( n \) lines of a data.frame, matrix, or a text object. Just a pretty call to \texttt{head} and \texttt{tail} or \texttt{View}

\textbf{Usage}

\begin{verbatim}
headTail(x, top=4, bottom=4, from=1, to=NULL, digits=2, hlength = 4, tlength = 4, ellipsis=TRUE)
headtail(x,hlength=4,tlength=4,digits=2,ellipsis=TRUE,from=1, to=NULL)
topBottom(x, top=4, bottom=4, from=1, to=NULL, digits=2, hlength = 4, tlength = 4)
quickView(x,top=8, bottom=8, from=1, to=NULL)
\end{verbatim}

\textbf{Arguments}

\begin{itemize}
\item \texttt{x} A matrix or data frame or free text
\item \texttt{top} The number of lines at the beginning to show
\item \texttt{bottom} The number of lines at the end to show
\item \texttt{digits} Round off the data to \texttt{digits}
\item \texttt{ellipsis} Separate the head and tail with dots (ellipsis)
\item \texttt{from} The first column to show (defaults to 1)
\item \texttt{to} The last column to show (defaults to the number of columns)
\item \texttt{hlength} The number of lines at the beginning to show (an alias for \texttt{top})
\item \texttt{tlength} The number of lines at the end to show (an alias for \texttt{bottom})
\end{itemize}

\textbf{Value}

The first top and last bottom lines of a matrix or data frame with an ellipsis in between. If the input is neither a matrix nor data frame, the output will be the first top and last bottom lines.

For each line, just columns starting at \texttt{from} and going to \texttt{to} will be displayed. By default, \texttt{from} = 1 and \texttt{to} = the last column.

topBottom is just a call to \texttt{headTail} with \texttt{ellipsis} = \texttt{FALSE} and returning a matrix output.

\texttt{quickView} is a call to \texttt{View} which opens a viewing window which is scrollable (if needed because the number of lines listed is more than a screen’s worth). \texttt{View} (and therefore \texttt{quickView}) is slower than \texttt{headTail} or \texttt{topBottom}.

\textbf{See Also}

\texttt{head} and \texttt{tail}
Examples

headTail(psychTools::iqitems,4,8,to=6) #the first 4 and last 6 items from 1 to 6
topBottom(psychTools::ability,from =2, to = 6) #the first and last 4 items from 2 to 6
headTail(psychTools::bfi,top=4, bottom=4,from =6,to=10) #the first and last 4 from 6 to 10
#not shown
#quickView(ability,hlength=10,tlength=10) #this loads a spreadsheet like table

---

**ICC**

Intraclass Correlations (ICC1, ICC2, ICC3 from Shrout and Fleiss)

**Description**

The Intraclass correlation is used as a measure of association when studying the reliability of raters. Shrout and Fleiss (1979) outline 6 different estimates, that depend upon the particular experimental design. All are implemented and given confidence limits. Uses either aov or lmer depending upon options. lmer allows for missing values.

**Usage**

ICC(x,missing=TRUE,alpha=.05,lmer=TRUE,check.keys=FALSE)

**Arguments**

- **x**: a matrix or dataframe of ratings
- **missing**: if TRUE, remove missing data – work on complete cases only (aov only)
- **alpha**: The alpha level for significance for finding the confidence intervals
- **lmer**: Should we use the lmer function from lme4? This handles missing data and gives variance components as well. TRUE by default.
- **check.keys**: If TRUE reverse those items that do not correlate with total score. This is not done by default.

**Details**

Shrout and Fleiss (1979) consider six cases of reliability of ratings done by k raters on n targets. ICC1: Each target is rated by a different judge and the judges are selected at random. (This is a one-way ANOVA fixed effects model and is found by (MSB- MSW)/(MSB+ (nr-1)*MSW))

ICC2: A random sample of k judges rate each target. The measure is one of absolute agreement in the ratings. Found as (MSB- MSE)/(MSB + (nr-1)*MSE + nr*(MSJ-MSE)/nc)

ICC3: A fixed set of k judges rate each target. There is no generalization to a larger population of judges. (MSB - MSE)/(MSB+ (nr-1)*MSE)

Then, for each of these cases, is reliability to be estimated for a single rating or for the average of k ratings? (The 1 rating case is equivalent to the average intercorrelation, the k rating case to the Spearman Brown adjusted reliability.)

ICC1 is sensitive to differences in means between raters and is a measure of absolute agreement. ICC2 and ICC3 remove mean differences between judges, but are sensitive to interactions of raters by judges. The difference between ICC2 and ICC3 is whether raters are seen as fixed or random effects.
ICC1k, ICC2k, ICC3K reflect the means of k raters.

The intraclass correlation is used if raters are all of the same “class”. That is, there is no logical way of distinguishing them. Examples include correlations between pairs of twins, correlations between raters. If the variables are logically distinguishable (e.g., different items on a test), then the more typical coefficient is based upon the inter-class correlation (e.g., a Pearson r) and a statistic such as alpha or omega might be used. alpha and ICC3k are identical.

If using the lmer option, then missing data are allowed. In addition the lme object returns the variance decomposition. (This is similar to testReTest which works on the items from two occasions.

The check.keys option by default reverses items that are negatively correlated with total score. A message is issued.

Value

|(results) | A matrix of 6 rows and 8 columns, including the ICCs, F test, p values, and confidence limits |
|summary | The anova summary table or the lmer summary table |
|stats | The anova statistics (converted from lmer if using lmer) |
|MSW | Mean Square Within based upon the anova |
|lme | The variance decomposition if using the lmer option |

Note

The results for the Lower and Upper Bounds for ICC(2,k) do not match those of SPSS 9 or 10, but do match the definitions of Shrout and Fleiss. SPSS seems to have been using the formula in McGraw and Wong, but not the errata on p 390. They seem to have fixed it in more recent releases (15).

Starting with psych 1.4.2, the confidence intervals are based upon (1-alpha)% at both tails of the confidence interval. This is in agreement with Shrout and Fleiss. Prior to 1.4.2 the confidence intervals were (1-alpha/2)% . However, at some point, this error slipped back again. It has been fixed in version 1.9.5 (5/21/19).

### iclуст

### iclust: Item Cluster Analysis – Hierarchical cluster analysis using psychometric principles

**Description**

A common data reduction technique is to cluster cases (subjects). Less common, but particularly useful in psychological research, is to cluster items (variables). This may be thought of as an alternative to factor analysis, based upon a much simpler model. The cluster model is that the correlations between variables reflect that each item loads on at most one cluster, and that items that load on those clusters correlate as a function of their respective loadings on that cluster and items that define different clusters correlate as a function of their respective cluster loadings and the intercluster correlations. Essentially, the cluster model is a Very Simple Structure factor model of complexity one (see VSS).

This function applies the iclust algorithm to hierarchically cluster items to form composite scales. Clusters are combined if coefficients alpha and beta will increase in the new cluster.

Alpha, the mean split half correlation, and beta, the worst split half correlation, are estimates of the reliability and general factor saturation of the test. (See also the omega function to estimate McDonald’s coefficients $\omega_h$ and $\omega_t$)

**Usage**

```r
iclуст(r.mat, nclusters=0, alpha=3, beta=1, beta.size=4, alpha.size=3, correct=TRUE, reverse.cluster=TRUE, reverse=TRUE, beta.min=.5, output=1, digits=2, labels=NULL, cut=0, n.iterations =0, title="ICLUST", plot=TRUE, weighted=TRUE, cor.gen=TRUE, SMC=TRUE, purify=TRUE, diagonal=FALSE)

ICLUST(r.mat, nclusters=0, alpha=3, beta=1, beta.size=4, alpha.size=3, correct=TRUE, reverse.cluster=TRUE, reverse=TRUE, beta.min=.5, output=1, digits=2, labels=NULL, cut=0, n.iterations =0, title="ICLUST", plot=TRUE, weighted=TRUE, cor.gen=TRUE, SMC=TRUE, purify=TRUE, diagonal=FALSE)
```

# iclust(r.mat) # use all defaults
# iclust(r.mat, nclusters =3) # use all defaults and if possible stop at 3 clusters
# ICLUST(r.mat, output =3) # long output shows clustering history
# ICLUST(r.mat, n.iterations =3) # clean up solution by item reassignment
Arguments

r.mat
A correlation matrix or data matrix/data.frame. (If r.mat is not square i.e, a correlation matrix, the data are correlated using pairwise deletion for Pearson correlations.

nclusters
Extract clusters until nclusters remain (default will extract until the other criteria are met or 1 cluster, whichever happens first). See the discussion below for alternative techniques for specifying the number of clusters.

alpha
Apply the increase in alpha criterion (0) never or for (1) the smaller, 2) the average, or 3) the greater of the separate alphas. (default = 3)

beta
Apply the increase in beta criterion (0) never or for (1) the smaller, 2) the average, or 3) the greater of the separate betas. (default = 1)

beta.size
Apply the beta criterion after clusters are of beta.size (default = 4)

alpha.size
Apply the alpha criterion after clusters are of size alpha.size (default = 3)

correct
Correct correlations for reliability (default = TRUE)

correct.cluster
Correct cluster -sub cluster correlations for reliability of the sub cluster, default is TRUE)

reverse
Reverse negative keyed items (default = TRUE)

beta.min
Stop clustering if the beta is not greater than beta.min (default = .5)

output
1) short, 2) medium, 3) long output (default = 1)

labels
vector of item content or labels. If NULL, then the colnames are used. If FALSE, then labels are V1 .. Vn

cut
sort cluster loadings > absolute(cut) (default = 0)

n.iterations
iterate the solution n.iterations times to “purify” the clusters (default = 0)

digits
Precision of digits of output (default = 2)

title
Title for this run

plot
Should ICLUST.rgraph be called automatically for plotting (requires Rgraphviz default=TRUE)

weighted
Weight the intercluster correlation by the size of the two clusters (TRUE) or do not weight them (FALSE)

cor.gen
When correlating clusters with subclusters, base the correlations on the general factor (default) or general + group (cor.gen=FALSE)

SMC
When estimating cluster-item correlations, use the smcs as the estimate of an item communality (SMC=TRUE) or use the maximum correlation (SMC=FALSE).

purify
Should clusters be defined as the original groupings (purify = FALSE) or by the items with the highest loadings on those original clusters? (purify = TRUE)

diagonal
Should the diagonal be included in the fit statistics. The default is not to include it. Prior to 1.2.8, the diagonal was included.

Details

Extensive documentation and justification of the algorithm is available in the original MBR 1979 https://personality-project.org/revelle/publications/iclust.pdf paper. Further discussion of the algorithm and sample output is available on the personality-project.org web page: https://personality-project.org/r/r.ICLUST.html
The results are best visualized using `ICLUST.graph`, the results of which can be saved as a dot file for the Graphviz program. https://www.graphviz.org/. The `iclust.diagram` is called automatically to produce cluster diagrams. The resulting diagram is not quite as pretty as what can be achieved in dot code but is quite adequate if you don’t want to use an external graphics program. With the installation of Rgraphviz, ICLUST can also provide cluster graphs.

A common problem in the social sciences is to construct scales or composites of items to measure constructs of theoretical interest and practical importance. This process frequently involves administering a battery of items from which those that meet certain criteria are selected. These criteria might be rational, empirical, or factorial. A similar problem is to analyze the adequacy of scales that already have been formed and to decide whether the putative constructs are measured properly. Both of these problems have been discussed in numerous texts, as well as in myriad articles. Proponents of various methods have argued for the importance of face validity, discriminant validity, construct validity, factorial homogeneity, and theoretical importance.

Revelle (1979) proposed that hierarchical cluster analysis could be used to estimate a new coefficient (beta) that was an estimate of the general factor saturation of a test. More recently, Zinbarg, Revelle, Yovel and Li (2005) compared McDonald’s Omega to Chronbach’s alpha and Revelle’s beta. They conclude that $\omega_h$, hierarchical is the best estimate. An algorithm for estimating $\omega_h$ is available as part of this package.

Revelle and Zinbarg (2009) discuss alpha, beta, and omega, as well as other estimates of reliability. The original ICLUST program was written in FORTRAN to run on CDC and IBM mainframes and was then modified to run in PC-DOS. The R version of iclust is a completely new version written for the psych package. Please email me if you want help with this version of iclust or if you desire more features.

A requested feature (not yet available) is to specify certain items as forming a cluster. That is, to do confirmatory cluster analysis.

The program currently has three primary functions: cluster, loadings, and graphics.

In June, 2009, the option of weighted versus unweighted beta was introduced. Unweighted beta calculates beta based upon the correlation between two clusters, corrected for test length using the Spearman-Brown prophecy formula, while weighted beta finds the average interitem correlation between the items within two clusters and then finds beta from this. That is, for two clusters A and B of size N and M with between average correlation rb, weighted beta is $(N+M)^2 rb/(Va +Vb + 2Cab)$. Raw (unweighted) beta is $2rab/(1+rab)$ where $rab = Cab/sqrt(VaVb)$. Weighted beta seems a more appropriate estimate and is now the default. Unweighted beta is still available for consistency with prior versions.

Also modified in June, 2009 was the way of correcting for item overlap when calculating the cluster-subcluster correlations for the graphic output. This does not affect the final cluster solution, but does produce slightly different path values. In addition, there are two ways to solve for the cluster-subcluster correlation.

Given the covariance between two clusters, $Cab$ with average $rab = Cab/(N*M)$, and cluster variances $Va$ and $Vb$ with $Va = N + N*(N-1)*ra$ then the correlation of cluster A with the combined cluster AB is either

a) $((N^2)ra + Cab)/(sqrt(Vab*Va))$ (option cor.gen=TRUE) or b) $(Va - N + Nra + Cab)/sqrt(Vab*Va)$ (option cor.gen=FALSE)

The default is to use cor.gen=TRUE.

Although iclust will give what it thinks is the best solution in terms of the number of clusters to extract, the user will sometimes disagree. To get more clusters than the default solution, just set the nclusters parameter to the number desired. However, to get fewer than meet the alpha and beta criteria, it is sometimes necessary to set alpha=0 and beta=0 and then set the nclusters to the desired number.
Clustering 24 tests of mental ability

A sample output using the 24 variable problem by Harman can be represented both graphically and in terms of the cluster order. The default is to produce graphics using the `diagram` functions. An alternative is to use the Rgraphviz package (from BioConductor). Because this package is sometimes hard to install, there is an alternative option (`ICLUST.graph`) to write dot language instructions for subsequent processing. This will create a graphic instructions suitable for any viewing program that uses the dot language. `ICLUST.rgraph` produces the dot code for Graphviz. Somewhat lower resolution graphs with fewer options are available in the `ICLUST.rgraph` function which requires Rgraphviz. Dot code can be viewed directly in Graphviz or can be tweaked using commercial software packages (e.g., OmniGraffle).

Note that for the Harman 24 variable problem, with the default parameters, the data form one large cluster. (This is consistent with the Very Simple Structure (VSS) output as well, which shows a clear one factor solution for complexity 1 data.)

An alternative solution is to ask for a somewhat more stringent set of criteria and require an increase in the size of beta for all clusters greater than 3 variables. This produces a 4 cluster solution.

It is also possible to use the original parameter settings, but ask for a 4 cluster solution.

At least for the Harman 24 mental ability measures, it is interesting to compare the cluster pattern matrix with the oblique rotation solution from a factor analysis. The factor congruence of a four factor oblique pattern solution with the four cluster solution is > .99 for three of the four clusters and > .97 for the fourth cluster. The cluster pattern matrix (returned as an invisible object in the output)

In September, 2012, the fit statistics (pattern fit and cluster fit) were slightly modified to (by default) not consider the diagonal (diagonal=FALSE). Until then, the diagonal was included in the cluster fit statistics. The pattern fit is analogous to factor analysis and is based upon the model = P x Structure where Structure is Pattern * Phi. Then R* = R - model and fit is the ratio of sum(r*^2)/sum(r^2) for the off diagonal elements.

Value

<table>
<thead>
<tr>
<th>title</th>
<th>Name of this analysis</th>
</tr>
</thead>
<tbody>
<tr>
<td>results</td>
<td>A list containing the step by step cluster history, including which pair was grouped, what were the alpha and betas of the two groups and of the combined group. Note that the alpha values are “standardized alphas” based upon the correlation matrix, rather than the raw alphas that will come from <code>scoreItems</code>. The print.psych and summary.psych functions will print out just the most important results.</td>
</tr>
<tr>
<td>corrected</td>
<td>The raw and corrected for alpha reliability cluster intercorrelations.</td>
</tr>
<tr>
<td>clusters</td>
<td>a matrix of -1,0, and 1 values to define cluster membership.</td>
</tr>
<tr>
<td>purified</td>
<td>A list of the cluster definitions and cluster loadings of the purified solution. These are sorted by importance (the eigenvalues of the clusters). The cluster membership from the original (O) and purified (P) clusters are indicated along with the cluster structure matrix. These item loadings are the same as those found by the <code>scoreItems</code> function and are found by correcting the item-cluster correlation for item overlap by summing the item-cluster covariances with all except that item and then adding in the smc for that item. These resulting correlations are then corrected for scale reliability. To show just the most salient items, use the cutoff option in <code>print.psych</code>.</td>
</tr>
</tbody>
</table>
cluster.fit, structure.fit, pattern.fit

There are a number of ways to evaluate how well any factor or cluster matrix reproduces the original matrix. Cluster fit considers how well the clusters fit if only correlations with clusters are considered. Structure fit evaluates $R = CC'$ while pattern fit evaluate $R = C^{-1} \phi C'$ where $C$ is the cluster loading matrix, and $\phi$ is the intercluster correlation matrix.

pattern

The pattern matrix loadings. Pattern is just $C^{-1} \phi$. The pattern matrix is conceptually equivalent to that of a factor analysis, in that the pattern coefficients are $b$ weights of the cluster to the variables, while the normal cluster loadings are correlations of the items with the cluster. The four cluster and four factor pattern matrices for the Harman problem are very similar.

Note

Iclust draws graphical displays with or without using Rgraphviz. Because of difficulties installing Rgraphviz on many systems, the default it not even try using it. With the introduction of the diagram functions, iclust now draws using iclust.diagram which is not as pretty as using Rgraphviz, but more stable. However, Rgraphviz can be used by using ICLUST.rgraph to produces slightly better graphics. It is also possible to export dot code in the dot language for further massaging of the graphic. This may be done using ICLUST.graph. This last option is probably preferred for nice graphics which can be massaged in any dot code program (e.g., graphviz (https://graphviz.org) or a commercial program such as OmniGraffle.

To view the cluster structure more closely, it is possible to save the graphic output as a pdf and then magnify this using a pdf viewer. This is useful when clustering a large number of variables.

In order to sort the clusters by cluster loadings, use iclust.sort.

By default, the correlations used for the similarity matrix are Pearson correlations. It is of course possible to tetrachoric or polychoric to form the correlation matrix for later analysis.

ICLUST.cluster

Function to form hierarchical cluster analysis of items

Description

The guts of the ICLUST algorithm. Called by ICLUST See ICLUST for description.

Usage

ICLUST.cluster(r.mat, ICLUST.options,smc.items)

Arguments

r.mat A correlation matrix
ICLUST.options A list of options (see ICLUST)
smc.items passed from the main program to speed up processing

Details

See ICLUST

Value

A list of cluster statistics, described more fully in ICLUST

comp1 Description of 'comp1'
comp2 Description of 'comp2'

Note

Although the main code for ICLUST is here in ICLUST.cluster, the more extensive documentation is for ICLUST.
iclust.diagram

iclust.diagram

Draw an ICLUST hierarchical cluster structure diagram

Description
Given a cluster structure determined by ICLUST, create a graphic structural diagram using graphic functions in the psych package. To create dot code to describe the ICLUST output with more precision, use ICLUST.graph. If Rgraphviz has been successfully installed, the alternative is to use ICLUST.rgraph.

Usage
iclust.diagram(ic, labels = NULL, short = FALSE, digits = 2, cex = NULL, min.size = NULL, e.size = 1, colors = c("black","blue"), main = "ICLUST diagram", cluster.names = NULL, marg = c(.5,.5,1.5,.5))

Arguments
ic
Output from ICLUST
labels
labels for variables (if not specified as rownames in the ICLUST output
short
if short=TRUE, variable names are replaced with Vn
digits
Round the path coefficients to digits accuracy
cex
The standard graphic control parameter for font size modifications. This can be used to make the labels bigger or smaller than the default values.
min.size
Don’t provide statistics for clusters less than min.size
e.size
size of the ellipses with the cluster statistics.
colors
positive and negative
main
The main graphic title
cluster.names
Normally, clusters are named sequentially C1 ... Cn. If cluster.names are specified, then these values will be used instead.
marg
Sets the margins to be narrower than the default values. Resets them upon return
iclust.diagram provides most of the power of ICLUST.rgraph without the difficulties involved in installing Rgraphviz. It is called automatically from ICLUST.

Following a request by Michael Kubovy, cluster.names may be specified to replace the normal C1 ... Cn names.

If access to a dot language graphics program is available, it is probably better to use the iclust.graph function to get dot output for offline editing.

Value

Graphical output summarizing the hierarchical cluster structure. The graph is drawn using the diagram functions (e.g., dia.curve, dia.arrow, dia.rect, dia.ellipse) created as a work around to Rgraphviz.

Note

Suggestions for improving the graphic output are welcome.

v9c <- ICLUST(v9)
test.data <- Harman74.cor$cov
ic.out <- ICLUST(test.data)
#now show how to relabel clusters
ic.bfi <- iclust(psychTools::bfi[1:25],beta=3) #find the clusters
ccluster.names <- rownames(ic.bfi$results) #get the old names
#change the names to the desired ones
cluster.names[c(16,19,15,18,20)] <- c("Neuroticism","Extra-Open","Agreeableness","Conscientiousness","Open")
#now show the new names
iclust.diagram(ic.bfi,cluster.names=cluster.names,min.size=4,e.size=1.75)
ICLUST.graph

ICLUST.graph

create control code for ICLUST graphical output

Description

Given a cluster structure determined by ICLUST, create dot code to describe the ICLUST output. To use the dot code, use either https://www.graphviz.org/ Graphviz or a commercial viewer (e.g., OmniGraffle). This function parallels ICLUST.rgraph which uses Rgraphviz.

Usage

ICLUST.graph(ic.results, out.file,min.size=1, short = FALSE, labels=NULL, size = c(8, 6), node.font = c("Helvetica", 14), edge.font = c("Helvetica", 12), rank.direction=c("RL","TB","LR","BT"), digits = 2, title = "ICLUST", ...)

Arguments

ic.results | output list from ICLUST
out.file | name of output file (defaults to console)
min.size | draw a smaller node (without all the information) for clusters < min.size – useful for large problems
short | if short==TRUE, don’t use variable names
labels | vector of text labels (contents) for the variables
size | size of output
node.font | Font to use for nodes in the graph
digits | number of digits to show
digit.font | Font to use for the labels of the arrows (edges)
title | any title
rank.direction | LR or RL
other options to pass | other options to pass

Details

Will create (or overwrite) an output file and print out the dot code to show a cluster structure. This dot file may be imported directly into a dot viewer (e.g., https://www.graphviz.org/). The “dot” language is a powerful graphic description language that is particular appropriate for viewing cluster output. Commercial graphics programs (e.g., OmniGraffle) can also read (and clean up) dot files.

ICLUST.graph takes the output from ICLUST results and processes it to provide a pretty picture of the results. Original variables shown as rectangles and ordered on the left hand side (if rank direction is RL) of the graph. Clusters are drawn as ellipses and include the alpha, beta, and size of the cluster. Edges show the cluster intercorrelations.

It is possible to trim the output to not show all cluster information. Clusters < min.size are shown as small ovals without alpha, beta, and size information.

Although it would be nice to process the dot code directly in R, the Rgraphviz package is difficult to use on all platforms and thus the dot code is written directly.
Value

Output is a set of dot commands written either to console or to the output file. These commands may then be used as input to any "dot" viewer, e.g., Graphviz.

ICLUST.rgraph

**Draw an ICLUST graph using the Rgraphviz package**

**Description**

Given a cluster structure determined by **ICLUST**, create a rgraphic directly using Rgraphviz. To create dot code to describe the **ICLUST** output with more precision, use **ICLUST.graph**. As an option, dot code is also generated and saved in a file. To use the dot code, use either https://www.graphviz.org/Graphviz or a commercial viewer (e.g., OmniGraffle).

**Usage**

```
ICLUST.rgraph(ic.results, out.file = NULL, min.size = 1, short = FALSE, labels = NULL, size = c(8, 6), node.font = c("Helvetica", 14), edge.font = c("Helvetica", 10), rank.direction=c("RL","TB","LR","BT"), digits = 2, title = "ICLUST",label.font=2, ...)```

**Arguments**

- `ic.results`: output list from ICLUST
- `out.file`: File name to save optional dot code.
- `min.size`: draw a smaller node (without all the information) for clusters < min.size – useful for large problems
ICLUST.rgraph

short if short==TRUE, don’t use variable names
labels vector of text labels (contents) for the variables
size size of output
node.font Font to use for nodes in the graph
edge.font Font to use for the labels of the arrows (edges)
rank.direction LR or TB or RL
digits number of digits to show
title any title
label.font The variable labels can be a different size than the other nodes. This is particularly helpful if the number of variables is large or the labels are long.
... other options to pass

Details

Will create (or overwrite) an output file and print out the dot code to show a cluster structure. This dot file may be imported directly into a dot viewer (e.g., https://www.graphviz.org/). The “dot” language is a powerful graphic description language that is particularly appropriate for viewing cluster output. Commercial graphics programs (e.g., OmniGraffle) can also read (and clean up) dot files.

ICLUST.rgraph takes the output from ICLUST results and processes it to provide a pretty picture of the results. Original variables shown as rectangles and ordered on the left hand side (if rank direction is RL) of the graph. Clusters are drawn as ellipses and include the alpha, beta, and size of the cluster. Edges show the cluster intercorrelations.

It is possible to trim the output to not show all cluster information. Clusters < min.size are shown as small ovals without alpha, beta, and size information.

Value

Output is a set of dot commands written either to console or to the output file. These commands may then be used as input to any "dot" viewer, e.g., Graphviz.

ICLUST.rgraph is a version of ICLUST.graph that uses Rgraphviz to draw on the screen as well.

Additional output is drawn to main graphics screen.

Note

Requires Rgraphviz

ICLUST.sort

Sort items by absolute size of cluster loadings

Description

Given a cluster analysis or factor analysis loadings matrix, sort the items by the (absolute) size of each column of loadings. Used as part of ICLUST and SAPA analyses. The columns are rearranged by the

Usage

```r
ICLUST.sort(ic.load, cut = 0, labels = NULL, keys = FALSE, clustsort = TRUE)
```

Arguments

- `ic.load`: The output from a factor or principal components analysis, or from ICLUST, or a matrix of loadings.
- `cut`: Do not include items in clusters with absolute loadings less than `cut`.
- `labels`: labels for each item.
- `keys`: should cluster keys be returned? Useful if clusters scales are to be scored.
- `clustsort`: TRUE will sort the clusters by their eigenvalues

Details

When interpreting cluster or factor analysis outputs, it is useful to group the items in terms of which items have their biggest loading on each factor/cluster and then to sort the items by size of the absolute factor loading.

A stable cluster solution will be one in which the output of these cluster definitions does not vary when clusters are formed from the clusters so defined.

With the `keys=TRUE` option, the resulting cluster keys may be used to score the original data or the correlation matrix to form clusters from the factors.

Value

- `sorted`: A data.frame of item numbers, item contents, and item x factor loadings.
- `cluster`: A matrix of -1, 0, 1s defining each item by the factor/cluster with the row wise largest absolute loading.

Note

Although part of the ICLUST set of programs, this is also more useful for factor or principal components analysis.
interp.median

Find the interpolated sample median, quartiles, or specific quantiles for a vector, matrix, or data frame

Description
For data with a limited number of response categories (e.g., attitude items), it is useful to treat each response category as a range with width, w and linearly interpolate the median, quartiles, or any quantile value within the median response.

Usage

interp.median(x, w = 1, na.rm = TRUE)
interp.quantiles(x, q = .5, w = 1, na.rm = TRUE)
interp.quartiles(x, w = 1, na.rm = TRUE)
interp.boxplot(x, w = 1, na.rm = TRUE)
interp.values(x, w = 1, na.rm = TRUE)
interp.qplot.by(y, x, w = 1, na.rm = TRUE, xlab = "group", ylab = "dependent", ylim = NULL, arrow.len = .05, typ = "b", add = FALSE, ...)

Arguments

x  input vector
q  quantile to estimate (0 < q < 1)
w  category width
y  input vector for interp.qplot.by
na.rm should missing values be removed
xlab x label
ylab Y label
ylim limits for the y axis
arrow.len length of arrow in interp.qplot.by
typ plot type in interp.qplot.by
add add the plot or not
... additional parameters to plotting function

Author(s)
William Revelle

References

https://personality-project.org/r/r.ICLUST.html

See Also

ICLUST.graph, ICLUST.cluster, cluster.fit, VSS, factor2cluster
Details

If the total number of responses is N, with median, M, and the number of responses at the median value, Nm >1, and Nb= the number of responses less than the median, then with the assumption that the responses are distributed uniformly within the category, the interpolated median is \( M - 0.5w + w*(N/2 - Nb)/Nm \).

The generalization to 1st, 2nd and 3rd quartiles as well as the general quantiles is straightforward.

A somewhat different generalization allows for graphic presentation of the difference between interpolated and non-interpolated points. This uses the interp.values function.

If the input is a matrix or data frame, quantiles are reported for each variable.

Value

im  interpolated median(quantile)

v   interpolated values for all data points

See Also

median

Examples

```r
interp.median(c(1,2,3,3,3))  # compare with median = 3
interp.median(c(1,2,2,5))
interp.quantiles(c(1,2,2,5),.25)

Description

Item Response Theory models individual responses to items by estimating individual ability (theta) and item difficulty (diff) parameters. This is an early and crude attempt to capture this modeling procedure. A better procedure is to use irt.fa.

Usage

irt.person.rasch(diff, items)
irt.0p(items)
irt.1p(delta, items)
irt.2p(delta, beta, items)

Arguments

diff A vector of item difficulties –probably taken from irt.item.diff.rasch
items A matrix of 0,1 items nrows = number of subjects, ncols = number of items
delta delta is the same as diff and is the item difficulty parameter
beta beta is the item discrimination parameter found in irt.discrim

Details

A very preliminary IRT estimation procedure. Given scores xij for ith individual on jth item
Classical Test Theory ignores item difficulty and defines ability as expected score : abilityi = theta(i) = x(i.) A zero parameter model rescales these mean scores from 0 to 1 to a quasi logistic scale ranging from - 4 to 4 This is merely a non-linear transform of the raw data to reflect a logistic mapping.

Basic 1 parameter (Rasch) model considers item difficulties (delta j): p(correct on item j for the ith subject ltheta i, deltaj) = 1/(1+exp(deltaj - thetai)) If we have estimates of item difficulty (delta), then we can find theta i by optimization

Two parameter model adds item sensitivity (beta j): p(correct on item j for subject i lthetai, deltaj, betaj) = 1/(1+exp(betaj *(deltaj- theta i))) Estimate delta, beta, and theta to maximize fit of model to data.

The procedure used here is to first find the item difficulties assuming theta = 0 Then find theta given those delus Then find beta given delta and theta.

This is not an "official" way to do IRT, but is useful for basic item development. See irt.fa and score.irt for far better options.

Value

a data.frame with estimated ability (theta) and quality of fit. (for irt.person.rasch)
a data.frame with the raw means, theta0, and the number of items completed

Note

Not recommended for serious use. This code is under development. Much better functions are in the ltm and eRm packages. Similar analyses can be done using irt.fa and score.irt.
**Description**

Although exploratory factor analysis and Item Response Theory seem to be very different models of binary data, they can provide equivalent parameter estimates of item difficulty and item discrimination. Tetrachoric or polychoric correlations of a data set of dichotomous or polytomous items may be factor analysed using a minimum residual or maximum likelihood factor analysis and the result loadings transformed to item discrimination parameters. The tau parameter from the tetrachoric/polychoric correlations combined with the item factor loading may be used to estimate item difficulties.

**Usage**

```r
irt.fa(x, nfactors=1, correct=TRUE, plot=TRUE, n.obs=NULL, rotate="oblimin", fm="minres", sort=FALSE, ...)  # rirt.select(x, y)
fa2irt(f, rho, plot=TRUE, n.obs=NULL)
```

**Arguments**

- `x`: A data matrix of dichotomous or discrete items, or the result of `tetrachoric` or `polychoric`
- `nfactors`: Defaults to 1 factor
- `correct`: If true, then correct the tetrachoric correlations for continuity. (See `tetrachoric`).
- `plot`: If TRUE, automatically call the `plot.irt` or `plot.poly` functions.
- `y`: the subset of variables to pick from the rho and tau output of a previous irt.fa analysis to allow for further analysis.
- `n.obs`: The number of subjects used in the initial analysis if doing a second analysis of a correlation matrix. In particular, if using the fm="minchi" option, this should be the matrix returned by `count.pairwise`.
- `rotate`: The default rotation is oblimin. See `fa` for the other options.
- `fm`: The default factor extraction is minres. See `fa` for the other options.
- `f`: The object returned from `fa`
- `rho`: The object returned from `polychoric` or `tetrachoric`. This will include both a correlation matrix and the item difficulty levels.
- `sort`: Should the factor loadings be sorted before preparing the item information tables. Defaults to FALSE as this is more useful for scoring items. For tabular output it is better to have sort=TRUE.
- `...`: Additional parameters to pass to the factor analysis function
**Details**

`irt.fa` combines several functions into one to make the process of item response analysis easier. Correlations are found using either tetrachoric or polychoric. Exploratory factor analyses with all the normal options are then done using `fa`. The results are then organized to be reported in terms of IRT parameters (difficulties and discriminations) as well as the more conventional factor analysis output. In addition, because the correlation step is somewhat slow, reanalyses may be done using the correlation matrix found in the first step. In this case, if it is desired to use the `fm="minchi"` factoring method, the number of observations needs to be specified as the matrix resulting from `pairwiseCount`.

The tetrachoric correlation matrix of dichotomous items may be factored using a (e.g.) minimum residual factor analysis function `fa` and the resulting loadings, $\lambda_i$, are transformed to discriminations by $\alpha = \frac{\lambda_i}{\sqrt{1-\lambda_i^2}}$.

The difficulty parameter, $\delta$, is found from the $\tau$ parameter of the tetrachoric or polychoric function.

$$\delta_i = \frac{\tau_i}{\sqrt{1-\lambda_i^2}}$$

Similar analyses may be done with discrete item responses using polychoric correlations and distinct estimates of item difficulty (location) for each item response.

The results may be shown graphically using `link(plot.irt)` for dichotomous items or `link(plot.poly)` for polytomous items. These called by plotting the `irt.fa` output, see the examples. For plotting there are three options: type = "ICC" will plot the item characteristic response function, type = "IIC" will plot the item information function, and type= "test" will plot the test information function. Invisible output from the plot function will return tables of item information as a function of several levels of the trait, as well as the standard error of measurement and the reliability at each of those levels.

The normal input is just the raw data. If, however, the correlation matrix has already been found using tetrachoric, polychoric, or a previous analysis using `irt.fa` then that result can be processed directly. Because `irt.fa` saves the rho and tau matrices from the analysis, subsequent analyses of the same data set are much faster if the input is the object returned on the first run. A similar feature is available in `omega`.

The output is best seen in terms of graphic displays. Plot the output from `irt.fa` to see item and test information functions.

The print function will print the item location and discriminations. The additional factor analysis output is available as an object in the output and may be printed directly by specifying the $fa$ object.

The `irt.select` function is a helper function to allow for selecting a subset of a prior analysis for further analysis. First run `irt.fa`, then select a subset of variables to be analyzed in a subsequent `irt.fa` analysis. Perhaps a better approach is to just plot and find the information for selected items.

The plot function for an `irt.fa` object will plot ICC (item characteristic curves), IIC (item information curves), or test information curves. In addition, by using the "keys" option, these three kinds of plots can be done for selected items. This is particularly useful when trying to see the information characteristics of short forms of tests based upon the longer form factor analysis.

The plot function will also return (invisibly) the information at multiple levels of the trait, the average information (area under the curve) as well as the location of the peak information for each item. These may be then printed or printed in sorted order using the sort option in print.

**Value**

- `irt` A list of Item location (difficulty) and discrimination
- `fa` A list of statistics for the factor analysis
rho The tetrachoric/polychoric correlation matrix
tau The tetrachoric/polychoric cut points

Note

`link(irt.fa)` makes use of the `tetrachoric` or `tetrachoric` functions. Both of these will use multiple cores if this is an option. To set these use options("mc.cores"=x) where x is the number of cores to use. (Macs default to 2, PCs seem to default to 1).

In comparing `irt.fa` to the `ltm` function in the `ltm` package or to the analysis reported in Kamata and Bauer (2008) the discrimination parameters are not identical, because the `irt.fa` reports them in units of the normal curve while `ltm` and Kamata and Bauer report them in logistic units. In addition, Kamata and Bauer do their factor analysis using a logistic error model. Their results match the `irt.fa` results (to the 2nd or 3rd decimal) when examining their analyses using a normal model. (With thanks to Akihito Kamata for sharing that analysis.)

`irt.fa` reports parameters in normal units. To convert them to conventional IRT parameters, multiply by 1.702. In addition, the location parameter is expressed in terms of difficulty (high positive scores imply lower frequency of response.)

The results of `irt.fa` can be used by `score.irt` for irt based scoring. First run `irt.fa` and then score the results using a two parameter model using `score.irt`.

irt.item.diff.rasch

Simple function to estimate item difficulties using IRT concepts

Description

Steps toward a very crude and preliminary IRT program. These two functions estimate item difficulty and discrimination parameters. A better procedure is to use irt.fa or the ltm package.

Usage

irt.item.diff.rasch(items)
irt.discrim(item.diff,theta,items)

Arguments

items a matrix of items
item.diff a vector of item difficulties (found by irt.item.diff)
theta ability estimate from irt.person.theta

Details

Item Response Theory (aka "The new psychometrics") models individual responses to items with a logistic function and an individual (theta) and item difficulty (diff) parameter.

irt.item.diff.rasch finds item difficulties with the assumption of theta=0 for all subjects and that all items are equally discriminating.

irt.discrim takes those difficulties and theta estimates from irt.person.rasch to find item discrimination (beta) parameters.

A far better package with these features is the ltm package. The IRT functions in the psych-package are for pedagogical rather than production purposes. They are believed to be accurate, but are not guaranteed. They do seem to be slightly more robust to missing data structures associated with SAPA data sets than the ltm package.

The irt.fa function is also an alternative. This will find tetrachoric or polychoric correlations and then convert to IRT parameters using factor analysis (fa).

# 4 0.3749 -0.7159
# 5 0.3377 -1.1264
#compare to ls$fa and ls$tau

#Kamata and Bauer (2008) logistic estimates
#1 0.826 2.773
#2 0.723 0.990
#3 0.891 0.249
#4 0.688 1.285
#5 0.657 2.053
**Value**

a vector of item difficulties or item discriminations.

**Note**

Under development. Not recommended for public consumption. See *irt.fa* and *score.irt* for far better options.

**irt.responses**  
*Plot probability of multiple choice responses as a function of a latent trait*

**Description**

When analyzing ability tests, it is important to consider how the distractor alternatives vary as a function of the latent trait. The simple graphical solution is to plot response endorsement frequencies against the values of the latent trait found from multiple items. A good item is one in which the probability of the distractors decrease and the keyed answer increases as the latent trait increases.

**Usage**

```r
irt.responses(theta, items, breaks = 11, show.missing=FALSE, show.legend=TRUE, legend.location="topleft", colors=NULL,...)
```

**Arguments**

- `theta`: The estimated latent trait (found, for example by using *score.irt*).
- `items`: A matrix or data frame of the multiple choice item responses.
- `breaks`: The number of levels of the theta to use to form the probability estimates. May be increased if there are enough cases.
- `show.legend`: Show the legend
- `show.missing`: For some SAPA data sets, there are a very large number of missing responses. In general, we do not want to show their frequency.
- `legend.location`: Choose among c("bottomright", "bottom", "bottomleft", "left", "topleft", "top", "topright", "right", "center", "none"). The default is "topleft".
- `colors`: if NULL, then use the default colors, otherwise, specify the color choices. The basic color palette is c("black", "blue", "red", "darkgreen", "gold2", "gray50", "cornflowerblue", "mediumorchid2").
- `...`: Other parameters for plots and points
Details

This function is a convenient way to analyze the quality of item alternatives in a multiple choice ability test. The typical use is to first score the test (using, e.g., `score.multiple.choice` according to some scoring key and to then find the `score.irt` based scores. Response frequencies for each alternative are then plotted against total score. An ideal item is one in which just one alternative (the correct one) has a monotonically increasing response probability.

Because of the similar pattern of results for IRT based or simple sum based item scoring, the function can be run on scores calculated either by `score.irt` or by `score.multiple.choice`. In the latter case, the number of breaks should not exceed the number of possible score alternatives.

Value

Graphic output

op <- par(op)

kaiser

Apply the Kaiser normalization when rotating factors

Description

Kaiser (1958) suggested normalizing factor loadings before rotating them, and then denormalizing them after rotation. The GPArotation package does not (by default) normalize, nor does the `fa` function. Then, to make it more confusing, varimax in stats does, Varimax in GPArotation does not. `kaiser` will take the output of a non-normalized solution and report the normalized solution.

Usage

```r
kaiser(f, rotate = "oblimin", m=4, pro.m=4)
```
**Arguments**

- **f**: A factor analysis output from `fa` or a factor loading matrix.
- **rotate**: Any of the standard rotations available in the GPArotation package.
- **m**: A parameter to pass to `Promax`.
- **pro.m**: A redundant parameter, which is used to replace `m` in calls to `Promax`.

**Details**

Best results if called from an unrotated solution. Repeated calls using a rotated solution will produce incorrect estimates of the correlations between the factors.

**Value**

See the values returned by GPArotation functions.

**Note**

Prepared in response to a question about why `fa` oblimin results are different from SPSS.

**Author(s)**

William Revelle

**References**

**See Also**

`fa`, `Promax`

**Examples**

```r
f3 <- fa(Thurstone, 3)
f3n <- kaiser(fa(Thurstone, 3, rotate="none"))
f3p <- kaiser(fa(Thurstone, 3, rotate="none"), rotate="Promax", m=3)
factor.congruence(list(f3, f3n, f3p))
```

---

**Description**

Henry Kaiser (1970) introduced an Measure of Sampling Adequacy (MSA) of factor analytic data matrices. Kaiser and Rice (1974) then modified it. This is just a function of the squared elements of the ‘image’ matrix compared to the squares of the original correlations. The overall MSA as well as estimates for each item are found. The index is known as the Kaiser-Meyer-Olkin (KMO) index.

**Usage**

```r
KMO(r)
```
Arguments

\( r \)  
A correlation matrix or a data matrix (correlations will be found)

Details

Let \( S^2 = \text{diag}(R^{-1})^{-1} \) and \( Q = SR^{-1}S \). Then \( Q \) is said to be the anti-image intercorrelation matrix. Let \( \text{sumr}^2 = \sum R^2 \) and \( \text{sumq}^2 = \sum Q^2 \) for all off diagonal elements of \( R \) and \( Q \), then \( SMA = \frac{\text{sumr}^2}{\text{sumr}^2 + \text{sumq}^2} \). Although originally MSA was \( 1 - \frac{\text{sumq}^2}{\text{sumr}^2} \) (Kaiser, 1970), this was modified in Kaiser and Rice, (1974) to be \( SMA = \frac{\text{sumr}^2}{\text{sumr}^2 + \text{sumq}^2} \). This is the formula used by Dziuban and Shirkey (1974) and by SPSS.

In his delightfully flamboyant style, Kaiser (1975) suggested that KMO > .9 were marvelous, in the .80s, meritorious, in the .70s, middling, in the .60s, mediocre, in the 50s, miserable, and less than .5, unacceptable.

An alternative measure of whether the matrix is factorable is the Bartlett test \texttt{cortest.bartlett} which tests the degree that the matrix deviates from an identity matrix.

Value

- MSA The overall Measure of Sampling Adequacy
- MSAi The measure of sampling adequacy for each item
- Image The Image correlation matrix (Q)

#compare to the results in Dziuban and Shirkey (1974)
logistic

Logistic transform from x to p and logit transform from p to x

Description
The logistic function (1/(1+exp(-x)) and logit function (log(p/(1-p)) are fundamental to Item Response Theory. Although just one line functions, they are included here for ease of demonstrations and in drawing IRT models. Also included is the logistic.grm for a graded response model.

Usage
logistic(x, d=0, a=1, c=0, z=1)
logit(p)
logistic.grm( x, d=0, a=1.5, c=0, z=1, r=2, s=c(-1.5,-.5,.5,1.5))

Arguments
x Any integer or real value
d Item difficulty or delta parameter
a The slope of the curve at x=0 is equivalent to the discrimination parameter in 2PL models or alpha parameter. Is either 1 in 1PL or 1.702 in 1PN approximations.
c Lower asymptote = guessing parameter in 3PL models or gamma
z The upper asymptote — in 4PL models
p Probability to be converted to logit value
r The response category for the graded response model
s The response thresholds

Details
These three functions are provided as simple helper functions for demonstrations of Item Response Theory. The one parameter logistic (1PL) model is also known as the Rasch model. It assumes items differ only in difficulty. 1PL, 2PL, 3PL and 4PL curves may be drawn by choosing the appropriate d (delta or item difficulty), a (discrimination or slope), c (gamma or guessing) and z (zeta or upper asymptote).
logit is just the inverse of logistic.
logistic.grm will create the responses for a graded response model for the rth category where cut-points are in s.

Value
p logistic returns the probability associated with x
x logit returns the real number associated with p

Author(s)
William Revelle
Examples

```r
curve(logistic(x,a=1.702),-3,3,ylab="Probability of x",
     main="Logistic transform of x",xlab="z score units")
#logistic with a=1.702 is almost the same as pnorm

curve(pnorm(x),add=TRUE,lty="dashed")
curve(logistic(x),add=TRUE)
text(2,.8, expression(alpha ==1))
text(2,1.0,expression(alpha==1.7))
curve(logistic(x),-4,4,ylab="Probability of x",
     main = "Logistic transform of x in logit units",xlab="logits")
curve(logistic(x,d=-1),add=TRUE)
curve(logistic(x,d=1),add=TRUE)
curve(logistic(x,c=.2),add=TRUE,lty="dashed")

text(0,.4,3)
text(1.,.4,4)
text(2.,.4,5)
```

lowerUpper

Combine two square matrices to have a lower off diagonal for one, upper off diagonal for the other

Description

When reporting correlation matrices for two samples (e.g., males and females), it is convenient to show them as one matrix, with entries below the diagonal representing one matrix, and entries above the diagonal the other matrix. It is also useful to compare a correlation matrix with the residuals from a fitted (e.g., factor) model.

Usage

```r
lowerUpper(lower, upper=NULL, diff=FALSE)
```

Arguments

- `lower`: A square matrix
- `upper`: A square matrix of the same size as the first (if omitted, then the matrix is converted to two symmetric matrices).
- `diff`: Find the difference between the first and second matrix and put the results in the above the diagonal entries.
Details

If just one matrix is provided (i.e., upper is missing), it is decomposed into two square matrices, one equal to the lower off diagonal entries, the other to the upper off diagonal entries. In the normal case two symmetric matrices are provided and combined into one non-symmetric matrix with the lower off diagonals representing the lower matrix and the upper off diagonals representing the upper matrix.

If diff is true, the upper off diagonal matrix reflects the differences between the two matrices.

Value

Either one matrix or a list of two

Author(s)

William Revelle

corPlot(t(diff12),numbers=TRUE,main="Bechtoldt1 and the differences from Bechtoldt2")

#Compare r and partial r
lower <- lowerCor(sat.act)
upper <- partial.r(sat.act)
both = lowerUpper(lower, upper)
corPlot(both,numbers=TRUE,main="r and partial r for the sat.act data set")
#now show the differences
both = lowerUpper(lower, upper, diff=TRUE)
corPlot(both,numbers=TRUE,main="Differences between r and partial r for the sat.act data set")

Description

When scoring items by forming composite scales either from the raw data using scoreItems or from the correlation matrix using cluster.cor, it used to be necessary to create a keys matrix. This is no longer necessary as most of the scoring functions will directly use a keys list. make.keys is just a short cut for creating a keys matrix. The keys matrix is a nvar x nscales matrix of -1,0, 1 and defines the membership for each scale. Items can be specified by location or by name.
Usage

make.keys(nvars, keys.list, item.labels = NULL, key.labels = NULL)
keys2list(keys, sign = TRUE)
selectFromKeys(keys.list)

Arguments

nvars Number of variables items to be scored, or the name of the data.frame/matrix to be scored
keys.list A list of the scoring keys, one element for each scale
item.labels Typically, just the colnames of the items data matrix.
key.labels Labels for the scales can be specified here, or in the key.list
keys A keys matrix returned from make.keys
sign if TRUE, prefix negatively keyed items with - (e.g., "-E2")

Details

The easiest way to prepare keys for scoreItems, scoreOverlap, scoreIrt.1pl, or scoreIrt.2pl is to specify a keys.list. This is just a list specifying the name of the scales to be scores and the direction of the items to be used.

In earlier versions (prior to 1.6.9) keys were formed as a matrix of -1, 0, and 1s for all the items using make.keys. This is no longer necessary, but make.keys is kept for compatibility with earlier versions.

There are three ways to create keys for the scoreItems, scoreOverlap, scoreIrt.1pl, or scoreIrt.2pl functions. One is to laboriously do it in a spreadsheet and then copy them into R. The other is to just specify them by item number in a list. make.keys allows one to specify items by name or by location or a mixture of both.

keys2list reverses the make.keys process and returns a list of scoring keys with the item names for each item to be keyed. If sign=FALSE, this is just a list of the items to be scored. (Useful for scoreIrt.2pl)

selectFromKeys will strip the signs from a keys.list and create a vector of item names (deleting duplicates) associated with those keys. This is useful if using a keys.list to define scales and then just selecting those items that are in subset of the keys.list. This is now done in the scoring functions in the interest of speed.

Since these scoring functions scoreItems, scoreOverlap, scoreIrt.1pl, or scoreIrt.2pl can now (> version 1.6.9) just take a keys.list as input, make.keys is not as important, but is kept for documentation purposes.

To address items by name it is necessary to specify item names, either by using the item.labels value, or by putting the name of the data file or the colnames of the data file to be scored into the first (nvars) position.

If specifying by number (location), then nvars is the total number of items in the object to be scored, not just the number of items used.

See the examples for the various options.

Note that make.keys was revised in Sept, 2013 to allow for keying by name.

It is also possible to do several make.keys operations and then combine them using superMatrix.
Value

keys

A `nvars` x `nkeys` matrix of -1, 0, or 1s describing how to score each scale. `nkeys` is the length of the `keys.list`.

See Also

`scoreItems`, `scoreOverlap`, `cluster.cor`, `superMatrix`

Examples

data( attitude )  # specify the items by location
key.list <- list( all = c(1,2,3,4,-5,6,7),
                  first = c(1,2,3),
                  last  = c(4,5,6,7) )

keys <- make.keys(7, key.list, item.labels = colnames( attitude ) )
keys

# now, undo this
new.keys.list <- keys2list( keys )  # note, these are now given the variable names

select <- selectFromKeys( key.list )

# scores <- score.items( keys, attitude )
# scores

# data( psychTools::bfi )
# first create the keys by location (the conventional way)
keys.list <- list( agree = c( -1,2:5 ), conscientious = c( 6:8,-9,-10 ),
                   extraversion = c( -11,-12,13:15 ), neuroticism = c( 16:20 ),
                   openness = c( 21,-22,23,24,-25 ) )
keys <- make.keys( 25, keys.list, item.labels = colnames( psychTools::bfi )[1:25] )
new.keys.list <- keys2list( keys )  # these will be in the form of variable names

# alternatively, create by a mixture of names and locations
keys.list <- list( agree = c( "-A1","A2","A3","A4","A5" ),
                   conscientious = c( "C1","C2","C2","-C4","-C5" ),
                   extraversion = c( "-E1","-E2","E3","E4","E5" ),
                   neuroticism = c( 16:20 ),
                   openness = c( 21,-22,23,24,-25 ) )
keys <- make.keys( psychTools::bfi, keys.list )  # specify the data file to be scored (bfi)
# or
keys <- make.keys( colnames( psychTools::bfi ), keys.list )  # specify the names of the variables
# to be used
# or
# specify the number of variables to be scored and their names in all cases
keys <- make.keys( 28, keys.list, colnames( psychTools::bfi ) )

scores <- score.items( keys, psychTools::bfi )
summary( scores )
Description

A useful way of showing the strength of many correlations with a particular criterion is the Manhattan plot. This is just a plot of correlations ordered by some keying variable. Useful to understand the basis of items used in bestScales.

Usage

```r
manhattan(x, criteria = NULL, keys = NULL, raw=TRUE, n.obs=NULL, abs = TRUE, ylab = NULL, labels = NULL, log.p = FALSE, ci=.05, pch = 21, main = "Manhattan Plot of", adjust="holm", ylim = NULL, digits=2, dictionary=NULL, ...)```

Arguments

- `x`: A matrix or data.frame of items or a correlation matrix.
- `criteria`: What column names should be predicted. If a separate file, what are the variables to predict.
- `keys`: A keys.list similar to that used in scoreItems
- `raw`: The default is raw data, the alternative is a correlation matrix
- `n.obs`: If given a correlation matrix, and showing log.p, we need the number of observations
- `abs`: Should we show the absolute value of the correlations.
- `ylab`: If NULL, will label as either correlations or log (10) of correlations
- `labels`: If NULL, will use the names of the keys
- `log.p`: Should we show the correlations (log.p = FALSE) or the log of the probabilities of the correlations (TRUE)
- `ci`: The probability for the upper and lower confidence intervals – bonferroni adjusted
- `pch`: The default plot character is a filled circle
- `main`: The title for each criterion
- `adjust`: Which adjustment for multiple correlations should be applied ("holm", "bonferroni", "none")
- `ylim`: If NULL will be the min and max of the data
- `digits`: Round off the results to digits
- `dictionary`: A dictionary of items
- `...`: Other graphic parameters

Details

When exploring the correlations of many items with a few criteria, it is useful to form scales from the most correlated items (see bestScales). To get a feeling of the distribution of items across various measures, we can display their correlations (or the log of the probabilities) grouped by some set of scale keys. May also be used to display and order correlations (rows) with a criteria (columns) if given a correlation as input (raw=FALSE).

Value

The correlations or the log p values are returned (invisibly)

  ,dictionary=psychTools::bfi.dictionary[1:2], raw=FALSE,abs=FALSE)
par <- op

psychTools::dfOrder(man,1,ascending=FALSE) # print out the items sorted on gender
```

mardia

Calculate univariate or multivariate (Mardia’s test) skew and kurtosis for a vector, matrix, or data.frame

Description

Find the skew and kurtosis for each variable in a data.frame or matrix. Unlike skew and kurtosis in e1071, this calculates a different skew for each variable or column of a data.frame/matrix. mardia applies Mardia’s tests for multivariate skew and kurtosis

Usage

```r
skew(x, na.rm = TRUE,type=3)
kurtosi(x, na.rm = TRUE, type=3)
mardia(x,na.rm = TRUE, plot=TRUE)
```
Arguments

- **x**: A data.frame or matrix
- **na.rm**: how to treat missing data
- **type**: See the discussion in describe.
- **plot**: Plot the expected normal distribution values versus the Mahalanobis distance of the subjects.

Details

given a matrix or data.frame x, find the skew or kurtosis for each column (for skew and kurtosis) or the multivariate skew and kurtosis in the case of mardia.

As of version 1.2.3, when finding the skew and the kurtosis, there are three different options available. These match the choices available in skewness and kurtosis found in the e1071 package (see Joanes and Gill (1998) for the advantages of each one).

If we define \( m_r = \frac{\sum (X - mx)^r}{n} \) then

Type 1 finds skewness and kurtosis by \( g_1 = m_3/(m_2)^{3/2} \) and \( g_2 = m_4/(m_2)^2 - 3 \).

Type 2 is \( G1 = g1 \times \sqrt{n} \times (n-1)/(n-2) \) and \( G2 = (n-1) \times [(n+1)g2 + 6]/((n-2)(n-3)) \).

Type 3 is \( b1 = [(n-1)/n]^{3/2}m_3/m_2^{3/2} \) and \( b2 = [(n-1)/n]^{3/2}m_4/m_2^2 \).

For consistency with e1071 and with the Joanes and Gill, the types are now defined as above.

However, from revision 1.0.93 to 1.2.3, kurtosi by default gives an unbiased estimate of the kurtosis (DeCarlo, 1997). Prior versions used a different equation which produced a biased estimate. (See the kurtosis function in the e1071 package for the distinction between these two formulae. The default, type 1 gave what is called type 2 in e1071. The other is their type 3.) For comparison with previous releases, specifying type = 2 will give the old estimate. These type numbers are now changed.

Value

- **skew**: if input is a matrix or data.frame, skew is a vector of skewes
- **kurtosi**: if input is a matrix or data.frame, kurtosi is a vector of kurtosis
- **bp1**: Mardia’s bp1 estimate of multivariate skew
- **bp2**: Mardia’s bp2 estimate of multivariate kurtosis
- **skew**: Mardia’s skew statistic
- **small.skew**: Mardia’s small sample skew statistic
- **p.skew**: Probability of skew
- **p.small**: Probability of small.skew
- **kurtosis**: Mardia’s multivariate kurtosis statistic
- **p.kurtosis**: Probability of kurtosis statistic
- **D**: Mahalanobis distance of cases from centroid

Note

The mean function supplies means for the columns of a data.frame, but the overall mean for a matrix. Mean will throw a warning for non-numeric data, but colMeans stops with non-numeric data. Thus, the function uses either mean (for data frames) or colMeans (for matrices). This is true for skew and kurtosi as well.

mat.sort  
Sort the elements of a correlation matrix to reflect factor loadings

Description
To see the structure of a correlation matrix, it is helpful to organize the items so that the similar items are grouped together. One such grouping technique is factor analysis. mat.sort will sort the items by a factor model (if specified), or any other order, or by the loadings on the first factor (if unspecified)

Usage
mat.sort(m, f = NULL)
matSort(m, f = NULL)

Arguments
m  A correlation matrix
f  A factor analysis output (i.e., one with a loadings matrix) or a matrix of weights

Details
The factor analysis output is sorted by size of the largest factor loading for each variable and then the matrix items are organized by those loadings. The default is to sort by the loadings on the first factor. Alternatives allow for ordering based upon any vector or matrix.
Value

A sorted correlation matrix, suitable for showing with corPlot.

Author(s)

William Revelle

See Also

fa, corPlot

Examples

data(Bechtoldt.1)
sorted <- mat.sort(Bechtoldt.1,fa(Bechtoldt.1,5))
corPlot(sorted,xlas=2) #vertical xaxis names

Description

It is sometimes convenient to add two vectors or matrices in an operation analogous to matrix multiplication. For matrices nXm and mYp, the matrix sum of the i,jth element of nSp = sum(over m) of iXm + mYj.

Usage

x %+% y

Arguments

x a n by m matrix (or vector if m = 1)
y a m by p matrix (or vector if m = 1)

Details

Used in such problems as Thurstonian scaling. Although not technically matrix addition, as pointed out by Krus, there are many applications where the sum or difference of two vectors or matrices is a useful operation. An alternative operation for vectors is outer(x,y,FUN="+") but this does not work for matrices.

Value

a n by p matrix of sums

mediate

Estimate and display direct and indirect effects of mediators and moderator in path models

Description

Find the direct and indirect effects of a predictor in path models of mediation and moderation. Bootstrap confidence intervals for the indirect effects. Mediation models are just extended regression models making explicit the effect of particular covariates in the model. Moderation is done by multiplication of the predictor variables. This function supplies basic mediation/moderation analyses for some of the classic problem types.

Usage

mediate(y, x, m=NULL, data, mod = NULL, z = NULL, n.obs = NULL, use = "pairwise", n.iter = 5000, alpha = 0.05, std = FALSE, plot=TRUE, zero=TRUE, main="Mediation")
mediate.diagram(medi,digits=2,ylim=c(3,7),xlim=c(-1,10),show.c=TRUE,main="Mediation model",cex=1,l.cex=1,...)
moderate.diagram(medi,digits=2,ylim=c(2,8),main="Moderation model", cex=1,l.cex=1,...)

Arguments

y The dependent variable (or a formula suitable for a linear model). If a formula, then this is of the form y ~ x +(m) -z (see details)
x One or more predictor variables
m One (or more) mediating variables
data A data frame holding the data or a correlation or covariance matrix.
mod A moderating variable, if desired
z Variables to partial out, if desired
n.obs If the data are from a correlation or covariance matrix, how many observations were used. This will lead to simulated data for the bootstrap.
use use="pairwise" is the default when finding correlations or covariances
n.iter Number of bootstrap resamplings to conduct
alpha Set the width of the confidence interval to be 1 - alpha
**Details**

When doing linear modeling, it is frequently convenient to estimate the direct effect of a predictor controlling for the indirect effect of a mediator. See Preacher and Hayes (2004) for a very thorough discussion of mediation. The `mediate` function will do some basic mediation and moderation models, with bootstrapped confidence intervals for the mediation/moderation effects.

Functionally, this is just regular linear regression and partial correlation with some different output. In the case of two predictor variables, X and M, and a criterion variable Y, then the direct effect of X on Y, labeled with the path c, is said to be mediated by the effect of x on M (path a) and the effect of M on Y (path b). This partial effect (a b) is said to mediate the direct effect of X –c–> Y: X –a -> M –b–> Y with X –c'–> Y where c' = c - ab.

Testing the significance of the ab mediation effect is done through bootstrapping many random resamples (with replacement) of the data.

For moderation, the moderation effect of Z on the relationship between X -> Y is found by taking the (centered) product of X and Z and then adding this XZ term into the regression. By default, the data are zero centered before doing moderation (product terms). This is following the advice of Cohen, Cohen, West and Aiken (2003). However, to agree with the analyses reported in Hayes (2013) we can set the zero=FALSE option to not zero center the data.

To partial out variables, either define them in the z term, or express as negative entries in the formula mode:

```r
y1 ~ x1 + x2 + (m1)+ (m2) -z will look for the effect of x1 and x2 on y, mediated through m1 and m2 after z is partialled out.
```

Moderated mediation is done by specifying a product term.

```r
y1 ~ x1 + x2*x3 + (m1)+ (m2) -z will look for the effect of x1, x2, x3 and the product of x2 and x3 on y, mediated through m1 and m2 after z is partialled out.
```

In the case of being provided just a correlation matrix, the bootstrapped values are based upon bootstrapping from data matching the original covariance/correlation matrix with the addition of normal errors. This allows us to test the mediation/moderation effect even if not given raw data. Moderation can not be done with just correlation matrix.

The function has been tested against some of the basic cases and examples in Hayes (2013) and the associated data sets.
Unless there is a temporal component that allows one to directly distinguish causal paths (time does not reverse direction), interpreting mediation models is problematic. Some people find it useful to compare the differences between mediation models where the causal paths (arrows) are reversed. This is a mistake and should not be done (Thoemmes, 2015).

For fine tuning the size of the graphic output, xlim and ylim can be specified in the mediate.diagram function. Otherwise, the graphics produced by mediate and moderate use the default xlim and ylim values.

Interaction terms (moderation) or mediated moderation can be specified as product terms.

### Value

- **total**: The total direct effect of x on y (c)
- **direct**: The beta effects of x (c’) and m (b) on y
- **indirect**: The indirect effect of x through m on y (c-ab)
- **mean.boot**: mean bootstrapped value of indirect effect
- **sd.boot**: Standard deviation of bootstrapped values
- **ci.quant**: The upper and lower confidence intervals based upon the quantiles of the bootstrapped distribution.
- **boot**: The bootstrapped values themselves.
- **a**: The effect of x on m
- **b**: The effect of m on y
- **b.int**: The interaction of x and mod (if specified)
- **data**: The original data plus the product term (if specified)

### Note

There are a number of other packages that do mediation analysis (e.g., sem and lavaan) and they are probably preferred for more complicated models. This function is supplied for the more basic cases, with 1.k y variables, 1..n x variables, 1..j mediators and 1..z variables to partial. The number of moderated effects is not limited, but more than 3rd order interactions are not very meaningful. It will not do two step mediation.

data=Spengler,n.obs = 1952, n.iter=50)
mod22 <- mediate(Income.50 + Educ.50 ~ IQ + Parental+ (Ed.11) + (Income.11) ,
data=Spengler,n.obs = 1952, n.iter=50)

Now, compare these models
mixedCor

Find correlations for mixtures of continuous, polytomous, and dichotomous variables

Description

For data sets with continuous, polytomous and dichotomous variables, the absolute Pearson correlation is downward biased from the underlying latent correlation. mixedCor finds Pearson correlations for the continuous variables, polychorics for the polytomous items, tetrachorics for the dichotomous items, and the polyserial or biserial correlations for the various mixed variables. Results include the complete correlation matrix, as well as the separate correlation matrices and difficulties for the polychoric and tetrachoric correlations.

Usage

mixedCor(data=NULL,c=NULL,p=NULL,d=NULL,smooth=TRUE,correct=.5,global=TRUE,ncat=8, use="pairwise",method="pearson",weight=NULL)

mixed.cor(x = NULL, p = NULL, d=NULL,smooth=TRUE, correct=.5,global=TRUE, ncat=8,use="pairwise",method="pearson",weight=NULL) #deprecated

Arguments

data The data set to be analyzed (either a matrix or dataframe)
c The names (or locations) of the continuous variables) (may be missing)
x A set of continuous variables (may be missing) or, if p and d are missing, the variables to be analyzed.
p A set of polytomous items (may be missing)
d A set of dichotomous items (may be missing)
smooth If TRUE, then smooth the correlation matrix if it is non-positive definite
correct When finding tetrachoric correlations, what value should be used to correct for continuity?
global For polychorics, should the global values of the tau parameters be used, or should the pairwise values be used. Set to local if errors are occurring.
ncat The number of categories beyond which a variable is considered "continuous".
use The various options to the cor function include "everything", "all.obs", "complete.obs", "na.or.complete", or "pairwise.complete.obs". The default here is "pairwise"
method The correlation method to use for the continuous variables. "pearson" (default), "kendall", or "spearman"
weight If specified, this is a vector of weights (one per participant) to differentially weight participants. The NULL case is equivalent of weights of 1 for all cases.
mixedCor

Details

This function is particularly useful as part of the Synthetic Aperture Personality Assessment (SAPA) (https://sapa-project.org) data sets where continuous variables (age, SAT V, SAT Q, etc) and mixed with polytomous personality items taken from the International Personality Item Pool (IPIP) and the dichotomous experimental IQ items that have been developed as part of SAPA (see, e.g., Revelle, Wilt and Rosenthal, 2010).

This is a very computationally intensive function which can be speeded up considerably by using multiple cores and using the parallel package. (See the note for timing comparisons.) This adjusts the number of cores to use when doing polychoric or tetrachoric. The greatest step in speed is going from 1 core to 2. This is about a 50% savings. Going to 4 cores seems to have about at 66% savings, and 8 a 75% savings. The number of parallel processes defaults to 2 but can be modified by using the options command: options("mc.cores"=4) will set the number of cores to 4.

Item response analyses using irt.fa may be done separately on the polytomous and dichotomous items in order to develop internally consistent scales. These scale may, in turn, be correlated with each other using the complete correlation matrix found by mixed.cor and using the score.items function.

This function is not quite as flexible as the hetcor function in John Fox’s polychor package.

Note that the variables may be organized by type of data: continuous, polytomous, and dichotomous. This is done by simply specifying c, p, and d. This is advantageous in the case of some continuous variables having a limited number of categories because of subsetting.

mixedCor is essentially a wrapper for cor, polychoric, tetrachoric, polydi and polyserial. It first identifies the types of variables, organizes them by type (continuous, polytomous, dichotomous), calls the appropriate correlation function, and then binds the resulting matrices together.

Value

rho The complete matrix
rx The Pearson correlation matrix for the continuous items
poly the polychoric correlation (poly$rho) and the item difficulties (poly$tau)
tetra the tetrachoric correlation (tetra$rho) and the item difficulties (tetra$tau)

Note

mixedCor was designed for the SAPA project (https://sapa-project.org) with large data sets with a mixture of continuous, dichotomous, and polytomous data. For smaller data sets, it is sometimes the case that the global estimate of the tau parameter will lead to unstable solutions. This may be corrected by setting the global parameter = FALSE.

mixedCor was added in April, 2017 to be slightly more user friendly. mixed.cor was deprecated in February, 2018.

When finding correlations between dummy coded SAPA data (e.g., of occupations), the real correlations are all slightly less than zero because of the ipsatized nature of the data. This leads to a non-positive definite correlation matrix because the matrix is no longer of full rank. Smoothing will correct this, even though this might not be desired. Turn off smoothing in this case.

Note that the variables no longer need to be organized by type of data: first continuous, then polytomous, then dichotomous. However, this automatic detection will lead to problems if the variables such as age are limited to less than 8 categories but those category values differ from the polytomous items. The fall back is to specify x, p, and d.

If the number of alternatives in the polychoric data differ and there are some dichotomous data, it is advisable to set correct=0.
Timing: For large data sets, `mixedCor` takes a while. Progress messages `progressBar` report what is happening but do not actually report the rate of progress. (The steps are initializing, Pearson r, polychorics, tetrachoric, polydi.) It is recommended to use the multicore option although the benefit between 2, 4 and 8 cores seems fairly small: For large data sets (e.g., 255K subjects, 950 variables), with 4 cores running in parallel (options("mc.cores=4") on a MacBook Pro with 2.8 Ghz Intel Core i7, it took 2,873/2,887 seconds elapsed time, 8,152/7,718 secs of user time, and 1,762/1,489 of system time (with and without smoothing). This is noticeably better than the 4,842 elapsed time (7,312 user, 1,459 system) for 2 cores but not much worse than running 8 virtual cores, with an elapsed time of 2,629, user time of 13,460, and system time of 2,679. On a Macbook Pro with 2 physical cores and a 3.3 GHz Intel Cor i7, running 4 multicores took 4,423 seconds elapsed time, 12,781 seconds of user time, and 2,605 system time. Running with 2 multicores, took slightly longer: 6,193 seconds elapsed time, 10,099 user time and 2,413 system time.

mssd

Find von Neuman’s Mean Square of Successive Differences

Description
Von Neuman et al. (1941) discussed the Mean Square of Successive Differences as a measure of variability that takes into account gradual shifts in mean. This is appropriate when studying errors in ballistics or variability and stability in mood when studying affect. For random data, this will be twice the variance, but for data with a sequential order and a positive autocorrelation, this will be much smaller. Since the mssd is just twice the variance - the autocorrelation, it is thus possible to also find the autocorrelation for a particular lag.
Usage

mssd(x, group=NULL, lag = 1, na.rm=TRUE)
rmssd(x, group=NULL, lag=1, na.rm=TRUE)
autoR(x, group=NULL, lag=1, na.rm=TRUE, use="pairwise")

Arguments

x a vector, data.frame or matrix
lag the lag to use when finding diff
group A column of the x data.frame to be used for grouping
na.rm Should missing data be removed?
use How to handle missing data in autoR.

Details

When examining multiple measures within subjects, it is sometimes useful to consider the variability of trial by trial observations in addition to the over all between trial variation. The Mean Square of Successive Differences (mssd) and root mean square of successive differences (rmssd) is just

$$\sigma^2 = \frac{\sum(x_i - x_{i+1})^2}{n - lag}$$

Where n-lag is used because there are only n-lag cases.

In the case of multiple subjects (groups) with multiple observations per subject (group), specify the grouping variable will produce output for each group.

Similar functions are available in the matrixStats package. However, the varDiff function in that package is variance of the difference rather than the MeanSquare. This is just the variance and standard deviation applied to the result from the diff function.

Perhaps useful when studying mood, the autoR function finds the autocorrelation for each item for the specified lag. It also returns the rmssd (root means square successive difference). This is done by finding the correlation of the lag data.

Value

The average squared successive difference (mssd) and the square root of the average squared successive difference (rmssd). Note that this is not the same as the standard deviation of the lagged differences.

**multi.hist**

*Multiple histograms with density and normal fits on one page*

**Description**

Given a matrix or data.frame, produce histograms for each variable in a "matrix" form. Include normal fits and density distributions for each plot.

The number of rows and columns may be specified, or calculated. May be used for single variables.

**Usage**

```
multi.hist(x,nrow=NULL,ncol=NULL,density=TRUE,freq=FALSE,bcol="white",
dcol=c("black","black"),dlty=c("dashed","dotted"),
main=NULL,mar=c(2,1,1,1),breaks=21,...)
```

```
histBy(x,var,group,density=TRUE,alpha=.5,breaks=21,col,xlab,
main="Histograms by group",...)
```

**Arguments**

```
x matrix or data.frame
var The variable in x to plot in histBy
group The name of the variable in x to use as the grouping variable
nrow number of rows in the plot
ncol number of columns in the plot
density density=TRUE, show the normal fits and density distributions
freq freq=FALSE shows probability densities and density distribution, freq=TRUE shows frequencies
bcol Color for the bars
```
multilevel.reliability

Find and plot various reliability/generallizability coefficients for multilevel data

Description

Various indicators of reliability of multilevel data (e.g., items over time nested within subjects) may be found using generalizability theory. A basic three way anova is applied to the data from which variance components are extracted. Random effects for a nested design are found by lme. These are, in turn, converted to several reliability/generalizability coefficients. An optional call to lme4 to use lmer may be used for unbalanced designs with missing data. mlArrange is a helper function to convert wide to long format. Data can be rearranged from wide to long format, and multiple lattice plots of observations overtime for multiple variables and multiple subjects are created.

dcol
The color(s) for the normal and the density fits. Defaults to black.
dlty
The line type (lty) of the normal and density fits. (specify the optional graphic parameter lwd to change the line size)
main
title for each panel will be set to the column name unless specified
mar
Specify the lower, left, upper and right hand side margin in lines – set to be tighter than normal default of c(5,4,4,2) + .1
xlab
Label for the x variable
breaks
The number of breaks in histBy (see hist)
alpha
The degree of transparency of the overlapping bars in histBy
col
A vector of colors in histBy (defaults to the rainbow)
...
additional graphic parameters (e.g., col)

multi.hist(sat.act,bcol="red")
multi.hist(sat.act,dcol="blue") #make both lines blue
multi.hist(sat.act,dcol= c("blue","red"),dlty=c("dotted", "solid"))
multi.hist(sat.act,freq=TRUE) #show the frequency plot
multi.hist(sat.act,nrow=2)
histBy(sat.act,"SATQ","gender")
multilevel.reliability

Usage

mlr(x, grp = "id", Time = "time", items = c(3:5), alpha=TRUE, icc=FALSE, aov=TRUE, lmer=FALSE, lme = TRUE, long=FALSE, values=NA, na.action="na.omit", plot=FALSE, main="Lattice Plot by subjects over time")
mlArrange(x, grp = "id", Time = "time", items = c(3:5), extra=NULL)
mlPlot(x, grp = "id", Time = "time", items = c(3:5), extra=NULL, col=c("blue","red","black","grey"), main="Lattice Plot by subjects over time",...)
multilevel.reliability(x, grp = "id", Time = "time", items = c(3:5), alpha=TRUE, icc=FALSE, aov=TRUE, lmer=FALSE, lme = TRUE, long=FALSE, values=NA, na.action="na.omit", plot=FALSE, main="Lattice Plot by subjects over time") # alias for mlr

Arguments

x A data frame with persons, time, and items.
grp Which variable specifies people (groups)
Time Which variable specifies the temporal sequence?
items Which items should be scored? Note that if there are multiple scales, just specify the items on one scale at a time. An item to be reversed scored can be specified by a minus sign. If long format, this is the column specifying item number.
alpha If TRUE, report alphas for every subject (default)
icc If TRUE, find ICCs for each person – can take a while
aov if FALSE, and if icc is FALSE, then just draw the within subject plots
lmer Should we use the lme4 package and lmer or just do the ANOVA? Requires the lme4 package to be installed. Necessary to do crossed designs with missing data but takes a very long time.
lme If TRUE, will find the nested components of variance. Relatively fast.
long Are the data in wide (default) or long format.
values If the data are in long format, which column name (number) has the values to be analyzed?
na.action How to handle missing data. Passed to the lme function.
plot If TRUE, show a lattice plot of the data by subject
extra Names or locations of extra columns to include in the long output. These will be carried over from the wide form and duplicated for all items. See example.
col Color for the lines in mlPlot. Note that items are categorical and thus drawn in alphabetical order. Order the colors appropriately.
main The main title for the plot (if drawn)
... Other parameters to pass to xyplot

Details

Classical reliability theory estimates the amount of variance in a set of observations due to a true score that varies over subjects. Generalizability theory extends this model to include other sources of variance, specifically, time. The classic studies using this approach are people measured over multiple time points with multiple items. Then the question is, how stable are various individual differences. Intraclass correlations (ICC) are found for each subject over items, and for each subject over time. Alpha reliabilities are found for each subject for the items across time.
More importantly, components of variance for people, items, time, and their interactions are found either by classical analysis of variance (aov) or by multilevel mixed effect modeling (lme). These are then used to form several different estimates of generalizability. Very thoughtful discussions of these procedure may be found in chapters by Shrout and Lane.

The variance components are the Between Person Variance $\sigma_p^2$, the variance between items $\sigma_{I1}^2$, over time $\sigma_T^2$, and their interactions.

Then, $R_{KF}$ is the reliability of average of all ratings across all items and times (Fixed time effects). (Shrout and Lane, Equation 6):

$$R_{KF} = \frac{\sigma_p^2 + \sigma_{I1}^2/n.I}{\sigma_p^2 + \sigma_{I1}^2/n.I + \sigma_T^2/(n.In.P)}$$

The generalizability of a single time point across all items (Random time effects) is just

$$R_{tR} = \frac{\sigma_p^2 + \sigma_{I1}^2/n.I}{\sigma_p^2 + \sigma_{I1}^2/n.I + \sigma_T^2/n.T + \sigma_T^2/n.T + \sigma_T^2/n.T + \sigma_e^2/(n.I)}$$

(Shrout and Lane equation 7 with a correction per Sean Lane.)

Generalizability of average time points across all items (Random effects). (Shrout and Lane, equation 8)

$$R_{kR} = \frac{\sigma_p^2 + \sigma_{I1}^2/n.I}{\sigma_p^2 + \sigma_{I1}^2/n.I + \sigma_T^2/n.T + \sigma_T^2/n.T + \sigma_T^2/n.T + \sigma_e^2/(n.I)}$$

Generalizability of change scores (Shrout and Lane, equation 9)

$$R_C = \frac{\sigma_T^2}{\sigma_T^2 + \sigma_e^2/(n.I)}$$

If the design may be thought of as fully crossed, then either aov or lmer can be used to estimate the components of variance. With no missing data and a balanced design, these will give identical answers. However aov breaks down with missing data and seems to be very slow and very memory intensive for large problems (5,919 seconds for 209 cases with with 88 time points and three items on a Mac Powerbook with a 2.8 GHZ Intel Core I7). The slowdown probably is memory related, as the memory demands increased to 22.62 GB of compressed memory. lmer will handle this design but is not nearly as slow (242 seconds for the 209 cases with 88 time points and three items) as the aov approach.

If the design is thought of as nested, rather than crossed, the components of variance are found using the lme function from nlme. This is very fast (114 cases with 88 time points and three items took 3.5 seconds).

The nested design leads to the generalizability of K random effects Nested (Shrout and Lane, equation 10):

$$R_{KRN} = \frac{\sigma_T^2}{\sigma_p^2 + \sigma_T^2/(n.I) + \sigma_T^2/(n.In.P)}$$

And, finally, to the reliability of between person differences, averaged over items. (Shrout and Lane, equation 11).

$$R_{CN} = \frac{\sigma_T^2/(n.P)}{\sigma_T^2/(n.P) + \sigma_e^2/(n.I)}$$
Unfortunately, when doing the nested analysis, \texttt{lme} will sometimes issue an obnoxious error about failing to converge. To fix this, turning off \texttt{lme} and just using \texttt{lmer} seems to solve the problem (i.e., set \texttt{lme=FALSE} and \texttt{lmer=TRUE}). (\texttt{lme} is part of core R and its namespace is automatically attached when loading \texttt{psych}). For many problems, \texttt{lmer} is not necessary and is thus not loaded. However sometimes it is useful. To use \texttt{lmer} it is necessary to have the \texttt{lme4} package installed. It will be automatically loaded if it is installed and requested. In the interests of making a 'thin' package, \texttt{lmer} is suggested, not required.

The input can either be in ‘wide’ or ‘long’ form. If in wide form, then specify the grouping variable, the ‘time’ variable, and the the column numbers or names of the items. (See the first example). If in long format, then what is the column (name or number) of the dependent variable. (See the second example.)

\texttt{mlArrange} takes a wide data.frame and organizes it into a ‘long’ data.frame suitable for a lattice \texttt{xyplot}. This is a convenient alternative to \texttt{stack}, particularly for unbalanced designs. The wide data frame is reorganized into a long data frame organized by grp (typically a subject id), by Time (typically a time varying variable, but can be anything, and then stacks the items within each person and time. Extra variables are carried over and matched to the appropriate grp and Time.

Thus, if we have N subjects over t time points for k items, in wide format for N \times t rows where each row has k items and e extra pieces of information, we get a N \times t \times k row by 4 + e column dataframe. The first four columns in the long output are id, time, values, and item names. The remaining columns are the extra values. These could be something such as a trait measure for each subject, or the situation in which the items are given.

\texttt{mlArrange} plots k items over the t time dimensions for each subject.

### Value

- \texttt{n.obs} Number of individuals
- \texttt{n.time} Maximum number of time intervals
- \texttt{n.items} Number of items
- \texttt{components} Components of variance associated with individuals, Time, Items, and their interactions.
- \texttt{RkF} Reliability of average of all ratings across all items and times (fixed effects).
- \texttt{R1R} Generalizability of a single time point across all items (Random effects)
- \texttt{RkR} Generalizability of average time points across all items (Random effects)
- \texttt{Rc} Generalizability of change scores over time.
- \texttt{RkRn} Generalizability of between person differences averaged over time and items
- \texttt{Rcn} Generalizability of within person variations averaged over items (nested structure)
- \texttt{ANOVA} The summary anova table from which the components are found (if done),
- \texttt{s.lmer} The summary of the \texttt{lmer} analysis (if done),
- \texttt{s.lme} The summary of the \texttt{lme} analysis (if done),
- \texttt{alpha} Within subject alpha over items and time.
- \texttt{summary.by.person} Summary table of ICCs organized by person,
- \texttt{summary.by.time} Summary table of ICCs organized by time.
- \texttt{ICC.by.person} A rather long list of ICCs by person.
- \texttt{ICC.by.time} Another long list of ICCs, this time for each time period,
- \texttt{long} The data (x) have been rearranged into long form for graphics or for further analyses using \texttt{lme}, \texttt{lmer}, or \texttt{aov} that require long form.

#make superwide into normal form (i.e., just return it to the original shrout data)

Xlong <- reshape(Xwide,idvar="Person",2:13)

#Now use these data for a multilevel reliability study, use the normal wide form output

mg <- mlr(shrout,grp="Person",Time="Time",items=3:5)

#which is the same as

#mg <- multilevel.reliability(shrout,grp="Person",Time="Time",items=c("Item1","Item2","Item3"),plot=TRUE)

#to show the lattice plot by subjects, set plot = TRUE

#Alternatively for long input (returned in this case from the prior run)

mlr(mg$long,grp="id",Time ="time",items="items", values="values",long=TRUE)
#example of mlArrange

# First, add two new columns to shrout and then convert to long output using mlArrange

total <- rowSums(shrout[3:5])
caseid <- rep(paste0("ID",1:5),4)
new.shrout <- cbind(shrout,total=total,case=caseid)

# now convert to long
headTail(new.long,6,6)

---

**omega**

Calculate McDonald's omega estimates of general and total factor saturation

---

**Description**

McDonald has proposed coefficient omega as an estimate of the general factor saturation of a test. One way to find omega is to do a factor analysis of the original data set, rotate the factors obliquely, do a Schmid Leiman transformation, and then find omega. This function estimates omega as suggested by McDonald by using hierarchical factor analysis (following Jensen). A related option is to define the model using omega and then perform a confirmatory (bi-factor) analysis using the sem or lavaan packages. This is done by omegaSem and omegaFromSem. omegaFromSem will convert appropriate sem/lavaan objects to find omega. Yet another option is to do the direct Schmid-Leiman of Waller.

**Usage**

omega(m,nfactors=3,fm="minres",n.iter=1,p=.05,poly=FALSE,key=NULL,
flip=TRUE,digits=2, title="Omega",sl=TRUE,labels=NULL,
plot=TRUE,n.obs=NA,rotate="oblimin",Phi=NULL,option="equal",covar=FALSE,...)

omegaSem(m,nfactors=3,fm="minres",key=NULL,flip=TRUE,digits=2,title="Omega",
sl=TRUE,labels=NULL, plot=TRUE,n.obs=NA,rotate="oblimin",
Phi = NULL, option="equal", lavaan=TRUE, ...)

omegah(m,nfactors=3,fm="minres",key=NULL,flip=TRUE,
digits=2,title="Omega",sl=TRUE,labels=NULL, plot=TRUE,
n.obs=NA,rotate="oblimin",Phi = NULL,option="equal",covar=FALSE,...)

omegaFromSem(fit,m=NULL,flip=TRUE,plot=TRUE)

omegaDirect(m,nfactors=3,fm="minres",rotate="oblimin",cut=.3,
plot=TRUE,main="Direct Schmid Leiman")
directSl(m,nfactors=3,fm="minres",rotate="oblimin",cut=.3)

**Arguments**

* m A correlation matrix, or a data.frame/matrix of data, or (if Phi) is specified, an oblique factor pattern matrix

* nfactors Number of factors believed to be group factors

* n.iter How many replications to do in omega for bootstrapped estimates
omega

fm  factor method (the default is minres) fm="pa" for principal axes, fm="minres" for a minimum residual (OLS) solution, fm="pc" for principal components (see note), or fm="ml" for maximum likelihood.

poly  should the correlation matrix be found using polychoric/tetrachoric or normal Pearson correlations

key  a vector of +/- 1s to specify the direction of scoring of items. The default is to assume all items are positively keyed, but if some items are reversed scored, then key should be specified.

flip  If flip is TRUE, then items are automatically flipped to have positive correlations on the general factor. Items that have been reversed are shown with a - sign.

p  probability of two tailed conference boundaries

digits  if specified, round the output to digits

title  Title for this analysis

main  main for this analysis (directSl)

cut  Loadings greater than cut are used in directSl

sl  If plotting the results, should the Schmid Leiman solution be shown or should the hierarchical solution be shown? (default sl=TRUE)

labels  If plotting, what labels should be applied to the variables? If not specified, will default to the column names.

plot  plot=TRUE (default) calls omega.diagram, plot =FALSE does not. If Rgraphviz is available, then omega.graph may be used separately.

n.obs  Number of observations - used for goodness of fit statistic

rotate  What rotation to apply? The default is oblimin, the alternatives include simplimax, Promax, cluster and target. target will rotate to an optional keys matrix (See target.rot)

Phi  If specified, then omega is found from the pattern matrix (m) and the factor intercorrelation matrix (Phi).

option  In the two factor case (not recommended), should the loadings be equal, emphasize the first factor, or emphasize the second factor. See in particular the option parameter in schmid for treating the case of two group factors.

covar  defaults to FALSE and the correlation matrix is found (standardized variables.) If TRUE, the do the calculations on the unstandardized variables and use covariances.

lavaan  if FALSE, will use John Fox’s sem package to do the omegaSem. If TRUE, will use Yves Rosseel’s lavaan package.

fit  The fitted object from lavaan or sem. For lavaan, this includes the correlation matrix and the variable names and thus m needs not be specified.

...  Allows additional parameters to be passed through to the factor routines.

Details

“Many scales are assumed by their developers and users to be primarily a measure of one latent variable. When it is also assumed that the scale conforms to the effect indicator model of measurement (as is almost always the case in psychological assessment), it is important to support such an interpretation with evidence regarding the internal structure of that scale. In particular, it is important to examine two related properties pertaining to the internal structure of such a scale. The first property relates to whether all the indicators forming the scale measure a latent variable in common.
The second internal structural property pertains to the proportion of variance in the scale scores (derived from summing or averaging the indicators) accounted for by this latent variable that is common to all the indicators (Cronbach, 1951; McDonald, 1999; Revelle, 1979). That is, if an effect indicator scale is primarily a measure of one latent variable common to all the indicators forming the scale, then that latent variable should account for the majority of the variance in the scale scores. Put differently, this variance ratio provides important information about the sampling fluctuations when estimating individuals’ standing on a latent variable common to all the indicators arising from the sampling of indicators (i.e., when dealing with either Type 2 or Type 12 sampling, to use the terminology of Lord, 1956). That is, this variance proportion can be interpreted as the square of the correlation between the scale score and the latent variable common to all the indicators in the infinite universe of indicators of which the scale indicators are a subset. Put yet another way, this variance ratio is important both as reliability and a validity coefficient. This is a reliability issue as the larger this variance ratio is, the more accurately one can predict an individual’s relative standing on the latent variable common to all the scale’s indicators based on his or her observed scale score. At the same time, this variance ratio also bears on the construct validity of the scale given that construct validity encompasses the internal structure of a scale.” (Zinbarg, Yovel, Revelle, and McDonald, 2006).

McDonald has proposed coefficient omega hierarchical ($\omega_h$) as an estimate of the general factor saturation of a test. Zinbarg, Revelle, Yovel and Li (2005) compare McDonald’s $\omega_h$ to Cronbach’s $\alpha$ and Revelle’s $\beta$. They conclude that $\omega_h$ is the best estimate. (See also Zinbarg et al., 2006 and Revelle and Zinbarg (2009)).

One way to find $\omega_h$ is to do a factor analysis of the original data set, rotate the factors obliquely, factor that correlation matrix, do a Schmid-Leiman (schmid) transformation to find general factor loadings, and then find $\omega_h$. Here we present code to do that.

$\omega_h$ differs as a function of how the factors are estimated. Four options are available, three use the $fa$ function but with different factoring methods: the default does a minres factor solution, fm="pa" does a principle axes factor analysis fm="mle" does a maximum likelihood solution; fm="pc" does a principal components analysis using (principal).

For ability items, it is typically the case that all items will have positive loadings on the general factor. However, for non-cognitive items it is frequently the case that some items are to be scored positively, and some negatively. Although probably better to specify which directions the items are to be scored by specifying a key vector, if flip =TRUE (the default), items will be reversed so that they have positive loadings on the general factor. The keys are reported so that scores can be found using the $scoreItems$ function. Arbitrarily reversing items this way can overestimate the general factor. (See the example with a simulated circumplex).

$\beta$, an alternative to $\omega_h$, is defined as the worst split half reliability (Revelle, 1979). It can be estimated by using ICLUS (a hierarchical clustering algorithm originally developed for main frames and written in Fortran and that is now part of the psych package. (For a very complimentary review of why the ICLUS algorithm is useful in scale construction, see Cooksey and Soutar, 2005)).

The omega function uses exploratory factor analysis to estimate the $\omega_h$ coefficient. It is important to remember that “A recommendation that should be heeded, regardless of the method chosen to estimate $\omega_h$, is to always examine the pattern of the estimated general factor loadings prior to estimating $\omega_h$. Such an examination constitutes an informal test of the assumption that there is a latent variable common to all of the scale’s indicators that can be conducted even in the context of EFA. If the loadings were salient for only a relatively small subset of the indicators, this would suggest that there is no true general factor underlying the covariance matrix. Just such an informal assumption test would have afforded a great deal of protection against the possibility of misinterpreting the misleading $\omega_h$ estimates occasionally produced in the simulations reported here.” (Zinbarg et al., 2006, p 137).
A simple demonstration of the problem of an omega estimate reflecting just one of two group factors can be found in the last example.

Diagnostic statistics that reflect the quality of the omega solution include a comparison of the relative size of the g factor eigen value to the other eigen values, the percent of the common variance for each item that is general factor variance (p2), the mean of p2, and the standard deviation of p2. Further diagnostics can be done by describing (describe) the Schmid results.

Although omega_h is uniquely defined only for cases where 3 or more subfactors are extracted, it is sometimes desired to have a two factor solution. By default this is done by forcing the schmid extraction to treat the two subfactors as having equal loadings.

There are three possible options for this condition: setting the general factor loadings between the two lower order factors to be “equal” which will be the sqrt(oblique correlations between the factors) or to “first” or “second” in which case the general factor is equated with either the first or second group factor. A message is issued suggesting that the model is not really well defined. This solution discussed in Zinbarg et al., 2007. To do this in omega, add the option="first" or option="second" to the call.

Although obviously not meaningful for a 1 factor solution, it is of course possible to find the sum of the loadings on the first (and only) factor, square them, and compare them to the overall matrix variance. This is done, with appropriate complaints.

In addition to $\omega_h$, another of McDonald’s coefficients is $\omega_t$. This is an estimate of the total reliability of a test.

McDonald’s $\omega_t$, which is similar to Guttman’s $\lambda_6$, but uses the estimates of uniqueness ($u^2$) from factor analysis to find $e^2_j$. This is based on a decomposition of the variance of a test score, $V_x$ into four parts: that due to a general factor, $\tilde{g}$, that due to a set of group factors, $\tilde{f}$, (factors common to some but not all of the items), specific factors, $\tilde{s}$ unique to each item, and $\tilde{e}$, random error. (Because specific variance can not be distinguished from random error unless the test is given at least twice, some combine these both into error).

Letting $\tilde{x} = \tilde{c} \tilde{g} + \tilde{A} \tilde{f} + \tilde{D} \tilde{s} + \tilde{e}$ then the communality of item $j$, based upon general as well as group factors, $h^2_j = c^2_j + \sum f^2_{ij}$ and the unique variance for the item $u^2_j = \sigma^2_j(1 - h^2_j)$ may be used to estimate the test reliability. That is, if $h^2_j$ is the communality of item $j$, based upon general as well as group factors, then for standardized items, $e^2_j = 1 - h^2_j$ and

$$\omega_t = \frac{\sum (1 - h^2_j)}{V_x} = 1 - \frac{\sum u^2_j}{V_x}$$

Because $h^2_j \geq r^2_{smc}$, $\omega_t \geq \lambda_6$.

It is important to distinguish here between the two $\omega$ coefficients of McDonald, 1978 and Equation 6.20a of McDonald, 1999, $\omega_t$ and $\omega_h$. While the former is based upon the sum of squared loadings on all the factors, the latter is based upon the sum of the squared loadings on the general factor.

$$\omega_h = \frac{\sum c^2_j}{V_x}$$

Another estimate reported is the omega for an infinite length test with a structure similar to the observed test (omega H asymptotic). This is found by

$$\omega_{limit} = \frac{\sum c^2_j}{\sum c^2_j + \sum A^2 f^2}$$

Following suggestions by Steve Reise, the Explained Common Variance (ECV) is also reported. This is the ratio of the general factor eigen value to the sum of all of the eigen values. As such,
it is a better indicator of unidimensionality than of the amount of test variance accounted for by a general factor.

The input to omega may be a correlation matrix or a raw data matrix, or a factor pattern matrix with the factor intercorrelations (Phi) matrix.

**omega** is an exploratory factor analysis function that uses a Schmid-Leiman transformation. **omegaSem** first calls **omega** and then takes the Schmid-Leiman solution, converts this to a confirmatory sem model and then calls the sem package to conduct a confirmatory model. \( \omega_h \) is then calculated from the CFA output. Although for well behaved problems, the efa and cfa solutions will be practically identical, the CFA solution will not always agree with the EFA solution. In particular, the estimated \( R^2 \) will sometimes exceed 1. (An example of this is the Harman 24 cognitive abilities problem.)

In addition, not all EFA solutions will produce workable CFA solutions. Model misspecifications will lead to very strange CFA estimates.

It is also possible to give **omega** a factor pattern matrix and the associated factor intercorrelation. In this case, the analysis will be done on these matrices. This is particularly useful if one is not satisfied with the exploratory EFA solutions and rotation options and somehow comes up with an alternative. (For instance, one might want to do a EFA using fm='pa' with a Kaiser normalized Promax solution with a specified m value.)

**omegaFromSem** takes the output from a sem model and uses it to find \( \omega_h \). The estimate of factor indeterminacy, found by the multiple \( R^2 \) of the variables with the factors, will not match that found by the EFA model. In particular, the estimated \( R^2 \) will sometimes exceed 1. (An example of this is the Harman 24 cognitive abilities problem.)

The notion of omega may be applied to the individual factors as well as the overall test. A typical use of omega is to identify subscales of a total inventory. Some of that variability is due to the general factor of the inventory, some to the specific variance of each subscale. Thus, we can find a number of different omega estimates: what percentage of the variance of the items identified with each subfactor is actually due to the general factor. What variance is common but unique to the subfactor, and what is the total reliable variance of each subfactor. These results are reported in omega.group object and in the last few lines of the normal output.

Finally, and still to be tested, is **omegaDirect** adapted from Waller (2017). This is a direct rotation to a Schmid-Leiman like solution without doing the hierarchical factoring (**directSl**). This rotation is then interpreted in terms of omega. It is included here to allow for comparisons with the alternative procedures omega and omegaSem. Preliminary analyses suggests that it produces inappropriate solutions for the case where there is no general factor.

Moral: Finding \( \omega_h \) is tricky and one should probably compare omega, omegaSem, omegaDirect and even iclust solutions to understand the differences.

The summary of the omega object is a reduced set of the most useful output.

The various objects returned from omega include:

**Value**

- **omega hierarchical**
  - The \( \omega_h \) coefficient
- **omega.lim**
  - The limit of \( \omega_h \) as the test becomes infinitely large
- **omega total**
  - The omega_t coefficient
- **alpha**
  - Cronbach’s \( \alpha \)
- **schmid**
  - The Schmid Leiman transformed factor matrix and associated matrices
- **schmid$s1**
  - The g factor loadings as well as the residualized factors
- **schmid$orthog**
  - Varimax rotated solution of the original factors
The oblimin or promax transformed factors

the correlation matrix of the oblique factors

The loadings on the higher order, g, factor of the oblimin factors

A vector of -1 or 1 showing which direction the items were scored.

a list of two elements, one suitable to give to the sem function for structure equation models, the other, to give to the lavaan package.

The output from a sem analysis

The summary statistics for the omega total, omega hierarchical (general) and omega within each group.

Factor score estimates are found for the Schmid-Leiman solution. To get scores for the hierarchical model see the note.

Various fit statistics

various fit statistics, see output

is an object that contains the fits for the OmegaSem output.

The direct SL rotated object (from omegaDirect)

The original, unrotated solution from omegaDirect

The cluster based target for rotation in directSl

Note

Requires the GPArotation package.

The default rotation uses oblimin from the GPArotation package. Alternatives include the simplimax function, as well as Promax or the promax rotations. promax will do a Kaiser normalization before applying Promax rotation.

If the factor solution leads to an exactly orthogonal solution (probably only for demonstration data sets), then use the rotate="Promax" option to get a solution.

omegasem requires the sem or lavaan packages. omegaFromSem uses the output from the sem or lavaan package.

omega may be run on raw data (finding either Pearson or tetrachoric/polychoric correlations, depending upon the poly option) a correlation matrix, a polychoric correlation matrix (found by e.g., polychoric), or the output of a previous omega run. This last case is particularly useful when working with categorical data using the poly=TRUE option. For in this case, most of the time is spent in finding the correlation matrix. The matrix is saved as part of the omega output and may be used as input for subsequent runs. A similar feature is found in irt.fa where the output of one analysis can be taken as the input to the subsequent analyses.

However, simulations based upon tetrachoric and polychoric correlations suggest that although the structure is better defined, that the estimates of omega are inflated over the true general factor saturation.

Omega returns factor scores based upon the Schmid-Leiman transformation. To get the hierarchical factor scores, it is necessary to do this outside of omega. See the example (not run).

Consider the case of the raw data in an object data. Then

f3 <- fa(data,3,scores="tenBerge",oblique.rotation=TRUE) f1 <- fa(f3$scores) hier.scores <- data.frame(f1$scores,f3$scores)

When doing fm="pc", principal components are done for the original correlation matrix, but minres is used when examining the intercomponent correlations. A warning is issued that the method was changed to minres for the higher order solution. omega is a factor model, and finding loadings using
principal components will overestimate the resulting solution. This is particularly problematic for the amount of group saturation, and thus the omega.group statistics are overestimates.

The last three lines of omega report "Total, General and Subset omega for each subset". These are available as the omega.group object in the output.

The last of these (omega group) is effectively what Steve Reise calls omegaS for the subset omega. The omega general is the amount of variance in the group that is accounted for by the general factor, the omega total is the amount of variance in the group accounted for by general + group.

This is based upon a cluster solution (that is to say, every item is assigned to one group) and this is why for first column the omega general and group do not add up to omega total. Some of the variance is found in the cross loadings between groups.

Reise and others like to report the ratio of the second line to the first line (what portion of the reliable variance is general factor) and the third row to the first (what portion of the reliable variance is within group but not general. This may be found by using the omega.group object that is returned by omega. (See the last example.)

If using the lavaan=TRUE option in omegaSem please note that variable names can not start with a digit (e.g. 4.Letter.Words in the Thurstone data set. The leading digit needs to be removed.

omegaSem will do an exploratory efa and omega, create (and return) the commands for doing either a sem or lavaan analysis. The commands are returned as the model object. This can be used for further sem/lavaan analyses.

Omega can also be found from an analysis done using lavaan or sem directly by calling omegaFromSem with the original correlation matrix and the fit of the sem/lavaan model. See the last (not run) example.

# f1 <- fa(f3$scores)

# om <- omega(data$observed,sl=FALSE) # draw the hierarchical figure
# The scores from om are based upon the Schmid-Leiman factors and although the g factor
# is identical, the group factors are not.
# This is seen in the following correlation matrix
Hierarchical factor structures represent the correlations between variables in terms of a smaller set of correlated factors which themselves can be represented by a higher order factor.

Two alternative solutions to such structures are found by the `omega` function. The correlated factors solutions represents the effect of the higher level, general factor, through its effect on the correlated factors. The other representation makes use of the Schmid Leiman transformation to find the direct effect of the general factor upon the original variables as well as the effect of orthogonal residual group factors upon the items.

Graphic presentations of these two alternatives are helpful in understanding the structure. `omega.graph` and `omega.diagram` draw both such structures. Graphs are drawn directly onto the graphics window or expressed in "dot" commands for conversion to graphics using implementations of Graphviz (if using `omega.graph`).

Using Graphviz allows the user to clean up the Rgraphviz output. However, if Graphviz and Rgraphviz are not available, use `omega.diagram`.

See the other structural diagramming functions, `fa.diagram` and `structure.diagram`.

In addition...
omega.graph

Usage

omega.graph(om.results, sl=TRUE, labels=NULL, flabels=NULL, cut=.2, gcut=.2, simple=TRUE, errors=FALSE, digits=1, e.size=.1, rsize=.15, side=3, main=NULL, cex=NULL, color.lines=TRUE, marg=c(.5,.5,.15,.5), adj=2, ...)
omega.graph(om.results, out.file = NULL, sl = TRUE, labels = NULL, size = c(8, 6), node.font = c("Helvetica", 14), edge.font = c("Helvetica", 10), rank.direction=c("RL","TB","LR","BT"), digits = 1, title = "Omega", ...)

Arguments

om.results The output from the omega function
out.file Optional output file for off line analysis using Graphviz
sl Orthogonal clusters using the Schmid-Leiman transform (sl=TRUE) or oblique clusters
labels variable labels
flabels Labels for the factors (not counting g)
size size of graphics window
node.font What font to use for the items
eedge.font What font to use for the edge labels
rank.direction Defaults to left to right
digits Precision of labels
cex control font size
color.lines Use black for positive, red for negative
marg The margins for the figure are set to be wider than normal by default
adj Adjust the location of the factor loadings to vary as factor mod 4 + 1
title Figure title
main main figure caption
... Other options to pass into the graphics packages
e.size the size to draw the ellipses for the factors. This is scaled by the number of variables.
cut Minimum path coefficient to draw
gcut Minimum general factor path to draw
simple draw just one path per item
sort sort the solution before making the diagram
side on which side should errors be drawn?
errors show the error estimates
rsize size of the rectangles

details

While omega.graph requires the Rgraphviz package, omega.diagram does not. codeomega requires the GPArotation package.
omega.graph

Value

- clust.graph: A graph object
- sem: A matrix suitable to be run through the `sem` function in the `sem` package.

Note

omega.graph requires rgraphviz. – omega requires GPArotation

outlier

Find and graph Mahalanobis squared distances to detect outliers

Description

The Mahalanobis distance is \( D^2 = (x - \mu)'\Sigma^{-1}(x - \mu) \) where \( \Sigma \) is the covariance of the \( x \) matrix. \( D^2 \) may be used as a way of detecting outliers in distribution. Large \( D^2 \) values, compared to the expected Chi Square values indicate an unusual response pattern. The mahalanobis function in stats does not handle missing data.

Usage

outlier(x, plot = TRUE, bad = 5, na.rm = TRUE, xlab, ylab, ...)

Arguments

- \( x \) A data matrix or data.frame
- \( plot \) Plot the resulting QQ graph
- \( bad \) Label the bad worst values
- \( na.rm \) Should missing data be deleted
- \( xlab \) Label for x axis
- \( ylab \) Label for y axis
- ... More graphic parameters, e.g., cex=.8

Details

Adapted from the mahalanobis function and help page from stats.

Value

The \( D^2 \) values for each case

\begin{itemize}
\item p.rep
\item Find the probability of replication for an \( F, t, \) or \( r \) and estimate effect size
\end{itemize}

Description

The probability of replication of an experimental or correlational finding as discussed by Peter Killeen (2005) is the probability of finding an effect in the same direction upon an exact replication. For articles submitted to Psychological Science, p.rep needs to be reported.

\( F, t, p \) and \( r \) are all estimates of the size of an effect. But \( F, t, \) and \( p \) also are also a function of the sample size. Effect size, \( d \) prime, may be expressed as differences between means compared to within cell standard deviations, or as a correlation coefficient. These functions convert \( p, F, \) and \( t \) to \( d \) prime and the \( r \) equivalent.

Usage

\begin{itemize}
\item p.rep(p = 0.05, n=NULL, twotailed = FALSE)
\item p.rep.f(F, df2, twotailed = FALSE)
\item p.rep.r(r, n, twotailed = TRUE)
\item p.rep.t(t, df, df2 = NULL, twotailed = TRUE)
\end{itemize}

Arguments

\begin{itemize}
\item p \hspace{1cm} conventional probability of statistic (e.g., of \( F, t, \) or \( r \))
\item F \hspace{1cm} The \( F \) statistic
\item df \hspace{1cm} Degrees of freedom of the \( t \)-test, or of the first group if unequal sizes
\item df2 \hspace{1cm} Degrees of freedom of the denominator of \( F \) or the second group in an unequal sizes \( t \) test
\item r \hspace{1cm} Correlation coefficient
\item n \hspace{1cm} Total sample size if using \( r \)
\item t \hspace{1cm} \( t \)-statistic if doing a \( t \)-test or testing significance of a regression slope
\item twotailed \hspace{1cm} Should a one or two tailed test be used?
\end{itemize}

Details

The conventional Null Hypothesis Significance Test (NHST) is the likelihood of observing the data given the null hypothesis of no effect. But this tells us nothing about the probability of the null hypothesis. Peter Killeen (2005) introduced the probability of replication as a more useful measure. The probability of replication is the probability that an exact replication study will find a result in the same direction as the original result.

p.rep is based upon a 1 tailed probability value of the observed statistic.
Other frequently called for statistics are estimates of the effect size, expressed either as Cohen’s d, Hedges g, or the equivalent value of the correlation, r.

For p.rep.t, if the cell sizes are unequal, the effect size estimates are adjusted by the ratio of the mean cell size to the harmonic mean cell size (see Rownow et al., 2000).

Value

- **p.rep** Probability of replication
- **dprime** Effect size (Cohen’s d) if more than just p is specified
- **prob** Probability of F, t, or r. Note that this can be either the one-tailed or two tailed probability value.
- **r.equivalent** For t-tests, the r equivalent to the t (see Rosenthal and Rubin(2003), Rosnow, Rosenthal, and Rubin, 2000)

Note

The p.rep value is the one tailed probability value of obtaining a result in the same direction.

References

Examples

```
p.rep(.05)  #probability of replicating a result if the original study had a  p = .05
p.rep.f(9.0,98)  #probability of replicating a result with F = 9.0 with 98 df
p.rep.r(.4,50)   #probability of replicating a result if r =.4 with n = 50
p.rep.t(3,98)    #probability of replicating a result if t = 3 with df =98
p.rep.t(2.14,84,14) #effect of equal sample sizes (see Rosnow et al.)
```

**paired.r**

*Test the difference between (un)paired correlations*

Description

Test the difference between two (paired or unpaired) correlations. Given 3 variables, x, y, z, is the correlation between xy different than that between xz? If y and z are independent, this is a simple t-test of the z transformed rs. But, if they are dependent, it is a bit more complicated.
Usage

paired.r(xy, xz, yz=NULL, n, n2=NULL, twotailed=TRUE)

Arguments

xy r(xy)

xz r(xz)

yz r(yz)

n Number of subjects for first group

n2 Number of subjects in second group (if not equal to n)

twotailed Calculate two or one tailed probability values

Details

To find the z of the difference between two independent correlations, first convert them to z scores using the Fisher r-z transform and then find the z of the difference between the two correlations. The default assumption is that the group sizes are the same, but the test can be done for different size groups by specifying n2.

If the correlations are not independent (i.e., they are from the same sample) then the correlation with the third variable r(yz) must be specified. Find a t statistic for the difference of these two dependent correlations.

Value

a list containing the calculated t or z values and the associated two (or one) tailed probability.

t t test of the difference between two dependent correlations

p probability of the t or of the z

z z test of the difference between two independent correlations

Author(s)

William Revelle

r.test for more tests of independent as well as dependent (paired) tests. p.rep.r for the probability of replicating a particular correlation. cor.test from stats for testing a single correlation and corr.test for finding the values and probabilities of multiple correlations. See also set.cor to do multiple correlations from matrix input.

Examples

paired.r(.5,.3,.4, 100) #dependent correlations

paired.r(.5,.3,NULL,100) #independent correlations same sample size

paired.r(.5,.3,NULL, 100, 64) # independent correlations, different sample sizes
Description

Adapted from the help page for pairs, pairs.panels shows a scatter plot of matrices (SPLOM), with bivariate scatter plots below the diagonal, histograms on the diagonal, and the Pearson correlation above the diagonal. Useful for descriptive statistics of small data sets. If lm=TRUE, linear regression fits are shown for both y by x and x by y. Correlation ellipses are also shown. Points may be given different colors depending upon some grouping variable. Robust fitting is done using lowess or loess regression. Confidence intervals of either the lm or loess are drawn if requested.

Usage

```r
## S3 method for class 'panels'
pairs(x, smooth = TRUE, scale = FALSE, density=TRUE, ellipses=TRUE,
      digits = 2, method="pearson", pch = 20, lm=FALSE, cor=TRUE, jiggle=FALSE, factor=2,
      hist.col="cyan", show.points=TRUE, rug=TRUE, breaks = "Sturges", cex.cor=1, wt=NULL,
      smoother=FALSE, stars=FALSE, ci=FALSE, alpha=.05, ...)
```

Arguments

- **x**: a data.frame or matrix
- **smooth**: TRUE draws loess smooths
- **scale**: TRUE scales the correlation font by the size of the absolute correlation.
- **density**: TRUE shows the density plots as well as histograms
- **ellipses**: TRUE draws correlation ellipses
- **lm**: Plot the linear fit rather than the LOESS smoothed fits.
- **digits**: the number of digits to show
- **method**: method parameter for the correlation ("pearson", "spearman", "kendall")
- **pch**: The plot character (defaults to 20 which is a '.').
- **cor**: If plotting regressions, should correlations be reported?
- **jiggle**: Should the points be jittered before plotting?
- **factor**: factor for jittering (1-5)
- **hist.col**: What color should the histogram on the diagonal be?
- **show.points**: If FALSE, do not show the data points, just the data ellipses and smoothed functions
- **rug**: if TRUE (default) draw a rug under the histogram, if FALSE, don’t draw the rug
- **breaks**: If specified, allows control for the number of breaks in the histogram (see the hist function)
- **cex.cor**: If this is specified, this will change the size of the text in the correlations. This allows one to also change the size of the points in the plot by specifying the normal cex values. If just specifying cex, it will change the character size, if cex.cor is specified, then cex will function to change the point size.
pairs.panels

wt If specified, then weight the correlations by a weights matrix (see note for some comments)
smoother If TRUE, then smooth.scatter the data points – slow but pretty with lots of subjects
stars For those people who like to show the significance of correlations by using magic astricks, set stars=TRUE
ci Draw confidence intervals for the linear model or for the loess fit, defaults to ci=FALSE. If confidence intervals are not drawn, the fitting function is lowess.
alpha The alpha level for the confidence regions, defaults to .05
...
other options for pairs

Details

Shamelessly adapted from the pairs help page. Uses panel.cor, panel.cor.scale, and panel.hist, all taken from the help pages for pairs. Also adapts the ellipse function from John Fox’s car package.

pairs.panels is most useful when the number of variables to plot is less than about 6-10. It is particularly useful for an initial overview of the data.

To show different groups with different colors, use a plot character (pch) between 21 and 25 and then set the background color to vary by group. (See the second example).

When plotting more than about 10 variables, it is useful to set the gap parameter to something less than 1 (e.g., 0). Alternatively, consider using cor.plot

In addition, when plotting more than about 100-200 cases, it is useful to set the plotting character to be a point. (pch=".")

Sometimes it useful to draw the correlation ellipses and best fitting loess without the points. (points.false=TRUE).

Value

A scatter plot matrix (SPLOM) is drawn in the graphic window. The lower off diagonal draws scatter plots, the diagonal histograms, the upper off diagonal reports the Pearson correlation (with pairwise deletion).

If lm=TRUE, then the scatter plots are drawn above and below the diagonal, each with a linear regression fit. Useful to show the difference between regression lines.

Note

If the data are either categorical or character, this is flagged with an astrix for the variable name. If character, they are changed to factors before plotting.

The wt parameter allows for scatter plots of the raw data while showing the weighted correlation matrix (found by using cor.wt). The current implementation uses the first two columns of the weights matrix for all analyses. This is useful, but not perfect. The use of this option would be to plot the means from a statsBy analysis and then display the weighted correlations by specifying the means and ns from the statsBy run. See the final (not run) example.

See Also

pairs which is the base from which pairs.panels is derived, cor.plot to do a heat map of correlations, and scatter.hist to draw a single correlation plot with histograms and best fitted lines.

To find the probability "significance" of the correlations using normal theory, use corr.test. To find confidence intervals using boot strapping procedures, use cor.ci. To graphically show confidence intervals, see cor.plot.upperLowerCi.
pairwiseCount

Examples

pairs.panels(attitude)  # see the graphics window
data(iris)
pairs.panels(iris[1:4],bg=c("red","yellow","blue")[iris$Species],
pch=21,main="Fisher Iris data by Species")  # to show color grouping

pairs.panels(iris[1:4],bg=c("red","yellow","blue")[iris$Species],
pch=21+as.numeric(iris$Species),main="Fisher Iris data by Species",hist.col="red")
# to show changing the diagonal

# to show 'significance'
pairs.panels(iris[1:4],bg=c("red","yellow","blue")[iris$Species],
pch=21+as.numeric(iris$Species),main="Fisher Iris data by Species",hist.col="red",stars=TRUE)

# demonstrate not showing the data points
data(sat.act)
pairs.panels(sat.act,show.points=FALSE)
# better yet is to show the points as a period
pairs.panels(sat.act,pch=".")
# show many variables with 0 gap between scatterplots
# data(bfi)
# pairs.panels(psychTools::bfi,show.points=FALSE,gap=0)

# plot raw data points and then the weighted correlations.
# output from statsBy
sb <- statsBy(sat.act,"education")
pairs.panels(sb$mean,wt=sb$n)  # report the weighted correlations
# compare with
pairs.panels(sb$mean)  # unweighed correlations

pairwiseCount(x, y = NULL, diagonal=TRUE)
pairwiseDescribe(x,y,diagonal=FALSE,...)
pairwiseImpute(keys,R,fix=FALSE)
pairwiseReport(x,y=NULL,cut=0,diagonal=FALSE,...)
pairwisePlot(x,y=NULL,upper=TRUE,diagonal=TRUE,labels=TRUE,show.legend=TRUE,n.legend=10,
colors=FALSE,gr=NULL,min.length=6,xlas=1,ylas=2,
main="Relative Frequencies",count=TRUE,...)
count.pairwise(x, y = NULL, diagonal=TRUE) #deprecated

Arguments

x       An input matrix, typically a data matrix ready to be correlated.
y       An optional second input matrix
diagonal if TRUE, then report the diagonal, else fill the diagonals with NA
...     Other parameters to pass to describe
keys    A keys.list specifying which items belong to which scale.
R       A correlation matrix to be described or imputed
cut     Report the item pairs and numbers with cell sizes less than cut
fix     If TRUE, then replace all NA correlations with the mean correlation for that
         within or between scale
upper   Should the upper off diagonal matrix be drawn, or left blank?
labels  if NULL, use column and row names, otherwise use labels
show.legend A legend (key) to the colors is shown on the right hand side
n.legend How many categories should be labelled in the legend?
colors   Defaults to FALSE and will use a grey scale. colors=TRUE use colors \ from
         the colorRampPalette from red through white to blue
min.length If not NULL, then the maximum number of characters to use in row/column
            labels
xlas     Orientation of the x axis labels (1 = horizontal, 0, parallel to axis, 2 perpendicular to axis)
ylas     Orientation of the y axis labels (1 = horizontal, 0, parallel to axis, 2 perpendicular to axis)
main     A title. Defaults to "Relative Frequencies"
gr       A color gradient: e.g., gr <- colorRampPalette(c("#B52127", "white", "#2171B5"))
         will produce slightly more pleasing (to some) colors. See next to last example
         of corPlot.
count    Should we count the number of pairwise observations using pairwiseCount, or
         just plot the counts for a matrix?

Details

When using Massively Missing Completely at Random (MMCAR) designs used by the SAPA
project, it is important to count the number of pairwise observations (pairwiseCount). If there
are pairs with 1 or fewer observations, these will produce NA values for correlations making subse-
quent factor analyses fa or reliability analyses omega or scoreOverlap impossible.

In order to identify item pairs with counts less than a certain value pairwiseReport reports the
names of those pairs with fewer than 'cut' observations. By default, it just reports the number of
offending items. With short=FALSE, the print will give the items with n.obs < cut. Even more
detail is available in the returned objects.

To remedy the problem of missing correlations, we impute the missing correlations using pairwiseImpute.
The technique takes advantage of the scale based structure of SAPA items. Items within a scale (e.g.
Letter Number Series similar to the ability items) are imputed to correlate with items from another
scale (e.g., Matrix Reasoning) at the average of these two between scale inter-item mean correlations. The average correlations within and between scales are reported by `pairwiseImpute` and if the fix parameter is specified, the imputed correlation matrix is returned.

Alternative methods of imputing these correlations are not yet implemented.

Value

result = matrix of counts of pairwise observations (if pairwiseCount)

av.r The average correlation value of the observed correlations within/between scales
count The number of observed correlations within/between each scale

percent The percentage of complete data by scale

imputed The original correlation matrix with NA values replaced by the mean correlation for items within/between the appropriate scale.

Examples

```r
x <- matrix(rnorm(900), ncol=6)
y <- matrix(rnorm(450), ncol=3)
x[x < 0] <- NA
ty[y > 1] <- NA

pairwiseCount(x)
pairwiseCount(y)
pairwiseCount(x,y)
pairwiseCount(x, diagonal=FALSE)
pairwiseDescribe(x, quant=c(.1,.25,.5,.75,.9))
```

# examine the structure of the ability data set
```r
keys <- list(ICAR16=colnames(psychTools::ability), reasoning =
cs(reason.4, reason.16, reason.17, reason.19),
letters=cs(letter.7, letter.33, letter.34, letter.58, letter.7),
matrix=cs(matrix.45, matrix.46, matrix.47, matrix.55),
rotate=cs(rotate.3, rotate.4, rotate.6, rotate.8))
pairwiseImpute(keys, psychTools::ability)
```

Description

Given a set of n items, form n/2 or n/3 mini scales or parcels of the most similar pairs or triplets of items. These may be used as the basis for subsequent scale construction or multivariate (e.g., factor) analysis.
Usage

```r
parcels(x, size = 3, max = TRUE, flip = TRUE, congruence = FALSE)
keysort(keys)
```

Arguments

- `x`: A matrix/dataframe of items or a correlation/covariance matrix of items
- `size`: Form parcels of size 2 or size 3
- `flip`: if flip = TRUE, negative correlations lead to at least one item being negatively scored
- `max`: Should item correlation/covariance be adjusted for their maximum correlation
- `congruence`: Should the correlations be converted to congruence coefficients?
- `keys`: Sort a matrix of keys to reflect item order as much as possible

Details

Items used in measuring ability or other aspects of personality are typically not very reliable. One suggestion has been to form items into homogeneous item composites (HICs), Factorially Homogeneous Item Dimensions (FHIDs) or mini scales (parcels). Parcelling may be done rationally, factorially, or empirically based upon the structure of the correlation/covariance matrix. `link{parcels}` facilitates the finding of parcels by forming a keys matrix suitable for using in `score.items`. These keys represent the n/2 most similar pairs or the n/3 most similar triplets.

The algorithm is straightforward: For size = 2, the correlation matrix is searched for the highest correlation. These two items form the first parcel and are dropped from the matrix. The procedure is repeated until there are no more pairs to form.

For size=3, the three items with the greatest sum of variances and covariances with each other is found. This triplet is the first parcel. All three items are removed and the procedure then identifies the next most similar triplet. The procedure repeats until n/3 parcels are identified.

Value

- `keys`: A matrix of scoring keys to be used to form mini scales (parcels) These will be in order of importance, that is, the first parcel (P1) will reflect the most similar pair or triplet. The keys may also be sorted by average item order by using the keysort function.

`score.items` to score the parcels or `iclust` for an alternative way of forming item clusters.
partial.r

Examples

```r
parcels(Thurstone)
keys <- parcels(psychTools::bfi)
keys <- keysort(keys)
score.items(keys,psychTools::bfi)
```

---

**partial.r**  
Find the partial correlations for a set (x) of variables with set (y) removed.

**Description**

A straightforward application of matrix algebra to remove the effect of the variables in the y set from the x set. Input may be either a data matrix or a correlation matrix. Variables in x and y are specified by location. If x and y are not specified, then the effect of all variables are partialled from all the other correlations.

**Usage**

```r
partial.r(data, x, y, use="pairwise", method="pearson")
```

**Arguments**

- `data`: A data or correlation matrix
- `x`: The variable names or locations associated with the X set.
- `y`: The variable names or locations associated with the Y set
- `use`: How should we treat missing data? The default is pairwise complete.
- `method`: Which method of correlation should we use, the default is pearson.

**Details**

There are two ways to use `partial.r`. One is to find the complete partial correlation matrix (that is, partial all the other variables out of each variable). This may be done by simply specify the raw data or correlation matrix. (In the case of raw data, correlations will be found according to use and method.) In this case, just specify the data matrix.

This is useful in the case of multiple regression. If we think of the data as an X matrix and a Y vector (D = X + Y) with correlations R. Then the partial correlations of the X predictors are just the last column of R^(-1). See the Tal.0r example below.

The second usage is to partial a set of variables(y) out of another set (x). It is sometimes convenient to partial the effect of a number of variables (e.g., sex, age, education) out of the correlations of another set of variables. This could be done laboriously by finding the residuals of various multiple correlations, and then correlating these residuals. The matrix algebra alternative is to do it directly. To find the confidence intervals and "significance" of the correlations, use the `corr.p` function with `n = n - s` where s is the nume of covariates.

Following a thoughtful request from Fransisco Wilheim, just find the correlations of the variables specified in the call (previously I had found the entire correlation matrix, which is a waste of time and breaks if some variables are non-numeric.)
Value

The matrix of partial correlations.

setCor for a similar application for regression. lowerMat to neatly show a correlation matrix, and corr.p to find the confidence intervals of a correlation.

Examples

```r
jen <- make.hierarchical()  #make up a correlation matrix
lowerMat(jen[1:5,1:5])
par.r <- partial.r(jen[,c(1,3,5),c(2,4)])
lowerMat(par.r)

cp <- corr.p(par.r,n=98)  #assumes the jen data based upon n =100.
print(cp,short=FALSE)  #show the confidence intervals as well
#partial all from all correlations.
lowerMat(partial.r(jen))

#Consider the Tal.Or data set.
lowerCor(Tal.Or)
#partial gender and age from these relations (they hardly change)
partial.r(Tal.Or[,1:4],cs(gender,age))
#find the partial correlations between the first three variables and the DV (reaction)
round(partial.r(Tal.Or[,1:4])[4,1:3],2)  #The partial correlations with the criterion
```

---

**phi**

\[
\text{Find the phi coefficient of correlation between two dichotomous variables}
\]

Description

Given a 1 x 4 vector or a 2 x 2 matrix of frequencies, find the phi coefficient of correlation. Typical use is in the case of predicting a dichotomous criterion from a dichotomous predictor.

Usage

\[
\text{phi(t, digits = 2)}
\]

Arguments

- `t`: a 1 x 4 vector or a 2 x 2 matrix
- `digits`: round the result to digits
Details

In many prediction situations, a dichotomous predictor (accept/reject) is validated against a dichotomous criterion (success/failure). Although a polychoric correlation estimates the underlying Pearson correlation as if the predictor and criteria were continuous and bivariate normal variables, and the tetrachoric correlation if both x and y are assumed to dichotomized normal distributions, the phi coefficient is the Pearson applied to a matrix of 0’s and 1s.

The phi coefficient was first reported by Yule (1912), but should not be confused with the Yule Q coefficient.

For a very useful discussion of various measures of association given a 2 x 2 table, and why one should probably prefer the Yule Q coefficient, see Warren (2008).

Given a two x two table of counts

\[
\begin{array}{ccc}
  a & b & a+b \text{ (R1)} \\
  c & d & c+d \text{ (R2)} \\
  a+c \text{ (C1)} & b+d \text{ (C2)} & a+b+c+d \text{ (N)}
\end{array}
\]

convert all counts to fractions of the total and then

\[
phi = \frac{(a- (a+b)*(a+c))}{\sqrt{(a+b)(c+d)(a+c)(b+d) }} = \frac{(a - R1 * C1)}{\sqrt{R1 * R2 * C1 * C2}}
\]

This is in contrast to the Yule coefficient, Q, where

\[
Q = \frac{(ad - bc)}{(ad+bc)}
\]

which is the same as

\[
\frac{[a- (a+b)*(a+c)]}{(ad+bc)}
\]

Since the phi coefficient is just a Pearson correlation applied to dichotomous data, to find a matrix of phis from a data set involves just finding the correlations using cor or \texttt{lowerCor} or \texttt{corr.test}.

Value

phi coefficient of correlation

\phi(x)
\end{align*}
\]
phi.demo  

Description

A not very interesting demo of what happens if bivariate continuous data are dichotomized. Basically a demo of r, phi, and polychor.

Usage

phi.demo(n=1000, r=.6, cuts=c(-2,-1,0,1,2))

Arguments

- n: number of cases to simulate
- r: correlation between latent and observed
- cuts: form dichotomized variables at the value of cuts

Details

A demonstration of the problem of different base rates on the phi correlation, and how these are partially solved by using the polychoric correlation. Not one of my more interesting demonstrations.

See https://personality-project.org/r/simulating-personality.html and https://personality-project.org/r/r.datageneration.html for better demonstrations of data generation.

Value

A matrix of correlations and a graphic plot. The items above the diagonal are the tetrachoric correlations, below the diagonal are raw correlations.

Author(s)

William Revelle

#show the result from phi2poly
#tetrachorics above the diagonal, phi below the diagonal
#round(demo$phis,2)

phi2tetra

Convert a phi coefficient to a tetrachoric correlation

Description

Given a phi coefficient (a Pearson r calculated on two dichotomous variables), and the marginal frequencies (in percentages), what is the corresponding estimate of the tetrachoric correlation?

Given a two x two table of counts

\[
\begin{array}{cc}
 a & b \\
 c & d \\
\end{array}
\]

The phi coefficient is \((a - (a+b)(a+c))/\sqrt{(a+b)(a+c)(b+d)(c+c)})\).

This function reproduces the cell entries for specified marginals and then calls the tetrachoric function. (Which was originally based upon John Fox’s polychor function.) The phi2poly name will become deprecated in the future.

Usage

phi2tetra(ph,m,n=NULL,correct=TRUE)
phi2poly(ph,cp,cc,n=NULL,correct=TRUE) #deprecated

Arguments

ph         phi
m         a vector of the selection ratio and probability of criterion. In the case where ph
          is a matrix, m is a vector of the frequencies of the selected cases
correct     When finding tetrachoric correlations, should we correct for continuity for small
          marginals. See tetrachoric for a discussion.
n         If the marginals are given as frequencies, what was the total number of cases?
cp         probability of the predictor – the so called selection ratio
cc         probability of the criterion – the so called success rate.

Details

used to require the mvtnorm package but this has been replaced with mnormt
Pinv

Value
a tetrachoric correlation

Author(s)
William Revelle

See Also
tetrachoric, Yule2phi.matrix, phi2poly.matrix

Examples
phi2tetra(.3,c(.5,.5))
#phi2poly(.3,.3,.7)

Description
Given a matrix of less than full rank, the conventional inverse function will fail. The pseudoinverse or generalized inverse resolves this problem by using just the postive values of the singular value decomposition d matrix. An adaptation of the ginv function from MASS and the pinv function from pracma.

Usage
Pinv(X, tol = sqrt(.Machine$double.eps))

Arguments
X A correlation or covariance matrix to analyze
tol A very small number. Reject values with eigen values less than tolerance

Details
The singular value decomposition of a matrix X is UdV where for full rank matrices, d is the vector of eigen values and U and V are the matrices of eigen vectors. The inverse is just U/d. If the matrix is less than full rank, many of the d values are effectively zero (at the limit of computational accuracy.) Thus, to solve matrix equations with matrices of less than full rank (e.g. the schmid Schmid-Leiman solution), we need to find the generalized inverse.

Value
The generalized inverse

Note
Adapted from the ginv function in MASS and the pinv function in pracma. Installed here to avoid loading those packages.
plot.psych

Plotting functions for the psych package of class “psych”

Description

Combines several plotting functions into one for objects of class “psych”. This can be used to plot the results of fa, irt.fa, VSS, ICLUST, omega, factor.pa, or principal.

Usage

```
## S3 method for class ‘psych’
plot(x, labels=NULL, ...)
## S3 method for class ‘irt’
plot(x, xlab, ylab, main, D, type=c("ICC", "IIC", "test"), cut=.3, labels=NULL,
     keys=NULL, xlim, ylim, y2lab, lncol="black", ...)
## S3 method for class ‘poly’
plot(x, D, xlab, ylab, xlim, ylim, main, type=c("ICC", "IIC", "test"), cut=.3, labels,
     keys=NULL, y2lab, lncol="black", ...)
## S3 method for class ‘residuals’
plot(x, main, type=c("qq", "chi", "hist", "cor"), std, bad=4,
     numbers=TRUE, upper=FALSE, diag=FALSE, ...)
```

Arguments

- **x**: The object to plot
- **labels**: Variable labels
- **xlab**: Label for the x axis – defaults to Latent Trait

Examples

```
round(Pinv(Thurstone) %*% Thurstone, 2)  # an identity matrix
sl <- schmid(Thurstone, 3)  # The schmid-leiman solution is less than full rank
F <- sl$s1[, 1:4]  # the SL solution is general + 3 group
R <- Thurstone  #
diag(R) <- sl$s1[, 5]  # the reproduced matrix (R - U2)
S <- t(Pinv(t(F) %*% F) %*% t(F) %*% R)  # the structure matrix
Phi <- t(S) %*% F %*% Pinv(t(F) %*% F)  # the factor covariances
```
ylab     Label for the y axis
xlim     The limits for the x axis
ylim     Specify the limits for the y axis
main     Main title for graph
type     "ICC" plots items, "IIC" plots item information, "test" plots test information, de-
          faults to IIC.. "qq" does a quantile plot, "chi" plots chi square distributions, "hist"
          shows the histogram, "cor" does a corPlot of the residuals.
D        The discrimination parameter
cut      Only plot item responses with discrimination greater than cut
keys     Used in plotting irt results from irt.fa.
y2lab    ylab for test reliability, defaults to "reliability"
bad      label the most 1.. bad items in residuals
numbers  if using the cor option in plot residuals, show the numeric values
upper    if using the cor option in plot residuals, show the upper off diagonal values
diag     if using the cor option in plot residuals, show the diagonal values
std      Standardize the residuals?
lncol    The color of the lines in the IRT plots. Defaults to all being black, but it is
         possible to specify lncol as a vector of colors to be used.
... other calls to plot

Details

Passes the appropriate values to plot. For plotting the results of irt.fa, there are three options:
type = "IIC" (default) will plot the item characteristic response function. type = "IIC" will plot the
item information function, and type= "test" will plot the test information function.

Note that plotting an irt result will call either plot.irt or plot.poly depending upon the type of data
that were used in the original irt.fa call.

These are calls to the generic plot function that are intercepted for objects of type "psych". More
precise plotting control is available in the separate plot functions. plot may be used for psych objects
returned from fa, irt.fa, ICLUST, omega, as well as principal

A "jiggle" parameter is available in the fa.plot function (called from plot.psych when the type is
a factor or cluster. If jiggle=TRUE, then the points are jittered slightly (controlled by amount)
before plotting. This option is useful when plotting items with identical factor loadings (e.g., when
comparing hypothetical models).

Objects from irt.fa are plotted according to "type" (Item informations, item characteristics, or
test information). In addition, plots for selected items may be done if using the keys matrix. Plots
of irt information return three invisible objects, a summary of information for each item at levels of
the trait, the average area under the curve (the average information) for each item as well as where
the item is most informative.

If plotting multiple factor solutions in plot.poly, then main can be a vector of names, one for each
factor. The default is to give main + the factor number.

It is also possible to create irt like plots based upon just a scoring key and item difficulties, or from
a factor analysis and item difficulties. These are not true IRT type analyses, in that the parameters
are not estimated from the data, but are rather indications of item location and discrimination for
arbitrary sets of items. To do this, find irt.stats.like and then plot the results.
plot.residuals allows the user to graphically examine the residuals of models formed by fa, irt.fa, omega, as well as principal and display them in a number of ways. "qq" will show quantiles of standardized or unstandardized residuals, "chi" will show quantiles of the squared standardized or unstandardized residuals plotted against the expected chi square values, "hist" will draw the histogram of the raw or standardized residuals, and "cor" will show a corPlot of the residual correlations.

Value

Graphic output for factor analysis, cluster analysis and item response analysis.

Note

More precise plotting control is available in the separate plot functions.

plot(resid(f4))
plot(resid(f4),main="Residuals from a 4 factor solution",qq=FALSE)
# not run
# data(bfi)
# e.irt <- irt.fa(bfi[11:15]) # just the extraversion items
# plot(e.irt) # the information curves
# ic <- iclust(test.data,3) # shows hierarchical structure
plot(ic) # plots loadings
#

polar

Convert Cartesian factor loadings into polar coordinates

Description

Factor and cluster analysis output typically presents item by factor correlations (loadings). Tables of factor loadings are frequently sorted by the size of loadings. This style of presentation tends to make it difficult to notice the pattern of loadings on other, secondary, dimensions. By converting to polar coordinates, it is easier to see the pattern of the secondary loadings.

Usage

polar(f, sort = TRUE)
Arguments

f A matrix of loadings or the output from a factor or cluster analysis program
sort sort=TRUE: sort items by the angle of the items on the first pair of factors.

Details

Although many uses of factor analysis/cluster analysis assume a simple structure where items have one and only one large loading, some domains such as personality or affect items have a more complex structure and some items have high loadings on two factors. (These items are said to have complexity 2, see VSS). By expressing the factor loadings in polar coordinates, this structure is more readily perceived.

For each pair of factors, item loadings are converted to an angle with the first factor, and a vector length corresponding to the amount of variance in the item shared with the two factors.

For a two dimensional structure, this will lead to a column of angles and a column of vector lengths. For n factors, this leads to n*(n-1)/2 columns of angles and an equivalent number of vector lengths.

Value

polar A data frame of polar coordinates

Examples

circ.data <- circ.sim(24,500)
circ.fa <- fa(circ.data,2)
circ.polar <- round(polar(circ.fa),2)
circ.polar
#compare to the graphic
cluster.plot(circ.fa)
polychor.matrix

Description
A set of deprecated functions that have replaced by Yule2tetra and Yule2phi. Some older correlation matrices were reported as matrices of Phi or of Yule correlations. That is, correlations were found from the two by two table of counts:

\[
\begin{array}{cc}
    a & b \\
    c & d \\
\end{array}
\]

Yule Q is \((ad - bc)/(ad+bc)\).

With marginal frequencies of a+b, c+d, a+c, b+d.

Given a square matrix of such correlations, and the proportions for each variable that are in the a + b cells, it is possible to reconver each correlation into a two by two table and then estimate the corresponding polychoric correlation (using John Fox’s polychor function).

Usage

Yule2poly.matrix(x, v)  #deprectated
phi2poly.matrix(x, v)  #deprectated
Yule2phi.matrix(x, v)  #deprectated

Arguments

x    a matrix of phi or Yule coefficients
v    A vector of marginal frequencies

Details
These functions call Yule2poly, Yule2phi or phi2poly for each cell of the matrix. See those functions for more details. See phi.demo for an example.

Value
A matrix of correlations

Author(s)
William Revelle

Examples
#demo <- phi.demo()
#compare the phi (lower off diagonal and polychoric correlations (upper off diagonal)
#show the result from poly.mat
predict.psych

# round(demo$tetrachoric$rho,2)
# show the result from phi2poly
# tetrachorics above the diagonal, phi below the diagonal
# round(demo$phis,2)

predict.psych  Prediction function for factor analysis, principal components (pca),

bestScales

Description

Finds predicted factor/component scores from a factor analysis or principal components analysis (pca) of data set A predicted to data set B. Predicted factor scores use the weights matrix used to find estimated factor scores, predicted components use the loadings matrix. Scores are either standardized with respect to the prediction sample or based upon the original data. Predicted scores from a bestScales model are based upon the statistics from the original sample.

Usage

## S3 method for class 'psych'
predict(object, data, old.data, options = NULL, ...)

Arguments

object      the result of a factor analysis, principal components analysis (pca) or bestScales of data set A
data        Data set B, of the same number of variables as data set A.
old.data    if specified, the data set B will be standardized in terms of values from the old data. This is probably the preferred option. This is done automatically if object is from bestScales
options     scoring options for bestScales objects ("best.keys","weights","optimal.keys","optimal.weights")
...         More options to pass to predictions

Value

Predicted factor/components/criteria scores. If predicting from either fa or pca, the scores are based upon standardized items where the standardization is either that of the original data (old.data) or of the prediction set. This latter case can lead to confusion if just a small number of predicted scores are found.

If the object is from bestScales, unit weighted scales are found (by default) using the best.keys and the predicted scores are then put into the metric of the means and standard deviations of the derivation sample. Other scoring key options may be specified using the "options" parameter. Possible values are best.keys","weights","optimal.keys","optimal.weights". See bestScales for details.

Note

Thanks to Reinhold Hatzinger for the suggestion and request and to Sarah McDougald for the bestScales prediction.

#the derivation sample
bs <- bestScales(psychTools::bfi[1:1400,], cs(gender,education,age),folds=10,p.keyed=.5)
pred <- predict(bs,psychTools::bfi[1401:2800])  #The prediction sample
cor2(pred,psychTools::bfi[1401:2800,26:28])  #the validity of the prediction
summary(bs)  #compare with bestScales cross validations
```

principal

Principal components analysis (PCA)

Description

Does an eigen value decomposition and returns eigen values, loadings, and degree of fit for a specified number of components. Basically it is just doing a principal components analysis (PCA) for n principal components of either a correlation or covariance matrix. Can show the residual correlations as well. The quality of reduction in the squared correlations is reported by comparing residual correlations to original correlations. Unlike princomp, this returns a subset of just the best nfactors. The eigen vectors are rescaled by the sqrt of the eigen values to produce the component loadings more typical in factor analysis.
Usage

principal(r, nfactors = 1, residuals = FALSE, rotate = "varimax", n.obs = NA, covar = FALSE, scores = TRUE, missing = FALSE, impute = "median", oblique.scores = TRUE, method = "regression", use = "pairwise", cor = "cor", correct = .5, weight = NULL, ...)

Arguments

- **r**: a correlation matrix. If a raw data matrix is used, the correlations will be found using pairwise deletions for missing values.
- **nfactors**: Number of components to extract
- **residuals**: FALSE, do not show residuals, TRUE, report residuals
- **rotate**: "none", "varimax", "quartimax", "promax", "oblimin", "simplimax", and "cluster" are possible rotations/transformation of the solution. See fa for all rotations available.
- **n.obs**: Number of observations used to find the correlation matrix if using a correlation matrix. Used for finding the goodness of fit statistics.
- **covar**: If false, find the correlation matrix from the raw data or convert to a correlation matrix if given a square matrix as input.
- **scores**: If TRUE, find component scores
- **missing**: if scores are TRUE, and missing = TRUE, then impute missing values using either the median or the mean
- **impute**: "median" or "mean" values are used to replace missing values
- **oblique.scores**: If TRUE (default), then the component scores are based upon the structure matrix. If FALSE, upon the pattern matrix.
- **method**: Which way of finding component scores should be used. The default is "regression"
- **weight**: If not NULL, a vector of length n.obs that contains weights for each observation. The NULL case is equivalent to all cases being weighted 1.
- **use**: How to treat missing data, use = "pairwise" is the default. See cor for other options.
- **cor**: How to find the correlations: "cor" is Pearson, "cov" is covariance, "tet" is tetrachoric, "poly" is polychoric, "mixed" uses mixedCor for a mixture of tetrachorics, polychorics, Pearsons, biserials, and polyserials, Yuleb is Yulebonett, Yuleq and YuleY are the obvious Yule coefficients as appropriate
- **correct**: When doing tetrachoric, polychoric, or mixed cor, how should we treat empty cells. (See the discussion in the help for tetrachoric.)
- **...**: other parameters to pass to functions such as factor.scores or the various rotation functions.

Details

Useful for those cases where the correlation matrix is improper (perhaps because of SAPA techniques).

There are a number of data reduction techniques including principal components analysis (PCA) and factor analysis (EFA). Both PC and FA attempt to approximate a given correlation or covariance matrix of rank n with matrix of lower rank (p).

\[ n R_n \approx_n F_{kk} F_{kk}' + U^2 \]

where k is much less than n. For principal components, the item uniqueness is assumed to be zero and all elements of
the correlation or covariance matrix are fitted. That is, \( nR_n \approx nF_n F_n' \). The primary empirical difference between a components versus a factor model is the treatment of the variances for each item. Philosophically, components are weighted composites of observed variables while in the factor model, variables are weighted composites of the factors. As the number of items increases, the difference between the two models gets smaller. Factor loadings are the asymptotic component loadings as the number of items gets larger.

For a \( n \times n \) correlation matrix, the \( n \) principal components completely reproduce the correlation matrix. However, if just the first \( k \) principal components are extracted, this is the best \( k \) dimensional approximation of the matrix.

It is important to recognize that rotated principal components are not principal components (the axes associated with the eigen value decomposition) but are merely components. To point this out, unrotated principal components are labelled as PCI, while rotated PCs are now labeled as RCi (for rotated components) and obliquely transformed components as TCi (for transformed components). (Thanks to Ulrike Gromping for this suggestion.)

Rotations and transformations are either part of psych (Promax and cluster), of base R (varimax), or of GPArotation (simplicax, quartimax, oblimin, etc.).

Of the various rotation/transformation options, varimax, Varimax, quartimax, bentlerT, geominT, and bifactor do orthogonal rotations. Promax transforms obliquely with a target matrix equal to the varimax solution. oblimin, quartimin, simplimax, bentlerQ, geominQ and biquartimin are oblique transformations. Most of these are just calls to the GPArotation package. The “cluster” option does a targeted rotation to a structure defined by the cluster representation of a varimax solution. With the optional “keys” parameter, the “target” option will rotate to a target supplied as a keys matrix. (See target.rot.)

The rotation matrix (rot.mat) is returned from all of these options. This is the inverse of the \( T \) object returned by the GPArotation package. The correlations of the factors may be found by \( \Phi = \theta^T \theta \)

Some of the statistics reported are more appropriate for (maximum likelihood) factor analysis rather than principal components analysis, and are reported to allow comparisons with these other models.

Although for items, it is typical to find component scores by scoring the salient items (using, e.g., scoreItems) component scores are found by regression where the regression weights are \( R^{-1} \lambda \) where \( \lambda \) is the matrix of component loadings. The regression approach is done to be parallel with the factor analysis function fa. The regression weights are found from the inverse of the correlation matrix times the component loadings. This has the result that the component scores are standard scores (mean=0, sd = 1) of the standardized input. A comparison to the scores from princomp shows this difference. princomp does not, by default, standardize the data matrix, nor are the components themselves standardized. The regression weights are found from the Structure matrix, not the Pattern matrix. If the scores are found with the covar option = TRUE, then the scores are not standardized but are just mean centered.

Jolliffe (2002) discusses why the interpretation of rotated components is complicated. Rencher (1992) discourages the use of rotated components. The approach used here is consistent with the factor analytic tradition. The correlations of the items with the component scores closely matches (as it should) the component loadings (as reported in the structure matrix).

The output from the print.psych function displays the component loadings (from the pattern matrix), the \( h2 \) (communalities) the \( u2 \) (the uniquenesses), com (the complexity of the component loadings for that variable (see below)). In the case of an orthogonal solution, \( h2 \) is merely the row sum of the squared component loadings. But for an oblique solution, it is the row sum of the (squared) orthogonal component loadings (remember, that rotations or transformations do not change the communality). This information is returned (invisibly) from the print function as the object Vaccounded.
Value

values  Eigen Values of all components – useful for a scree plot
rotation which rotation was requested?
n.obs  number of observations specified or found
communality  Communality estimates for each item. These are merely the sum of squared factor loadings for that item.
complexity  Hoffman’s index of complexity for each item. This is just $\frac{\sum a_i^2}{\sum a_i^4}$ where $a_i$ is the factor loading on the $i$th factor. From Hofmann (1978), MBR. See also Pettersson and Turkheimer (2010).
loadings  A standard loading matrix of class “loadings”
fit  Fit of the model to the correlation matrix
fit.off  how well are the off diagonal elements reproduced?
residual  Residual matrix – if requested
dof  Degrees of Freedom for this model. This is the number of observed correlations minus the number of independent parameters (number of items * number of factors - $n_f^2(n_f-1)/2$. That is, dof = $n_f(n_f-1)/2 - n_f + n_f^2(n_f-1)/2$.
objective  value of the function that is minimized by maximum likelihood procedures. This is reported for comparison purposes and as a way to estimate chi square goodness of fit. The objective function is $f = (trace((FF' + U2)^{-1}R) - log(|(FF' + U2)^{-1}R|) - n.items$. Because components do not minimize the off diagonal, this fit will be not as good as for factor analysis. It is included merely for comparison purposes.
STATISTIC  If the number of observations is specified or found, this is a chi square based upon the objective function, $f$. Using the formula from `factanal`:

$$\chi^2 = (n.obs - 1 - (2 * p + 5)/6 - (2 * factors)/3)) * f$$

PVAL  If n.obs > 0, then what is the probability of observing a chisquare this large or larger?
phi  If oblique rotations (using oblimin from the GPArotation package) are requested, what is the interfactor correlation.
scores  If scores=TRUE, then estimates of the factor scores are reported
weights  The beta weights to find the principal components from the data
R2  The multiple R square between the factors and factor score estimates, if they were to be found. (From Grice, 2001) For components, these are of course 1.0.
valid  The correlations of the component score estimates with the components, if they were to be found and unit weights were used. (So called course coding).
rot.mat  The rotation matrix used to produce the rotated component loadings.

Note

By default, the accuracy of the varimax rotation function seems to be less than the Varimax function. This can be enhanced by specifying eps=1e-14 in the call to principal if using varimax rotation. Furthermore, note that Varimax by default does not apply the Kaiser normalization, but varimax does. Gottfried Helms compared these two rotations with those produced by SPSS and found identical values if using the appropriate options. (See the last two examples.)

The ability to use different kinds of correlations was added in versin 1.9.12.31 to be compatible with the options in fa.

round(p$Vaccounted,2) # the amount of variance accounted for is returned as an object of print
print.psych

Print and summary functions for the psych class

Description
Give limited output (print) or somewhat more detailed (summary) for most of the functions in psych.

Usage

## S3 method for class 'psych'
print(x, digits=2, all=FALSE, cut=NULL, sort=FALSE, short=TRUE, lower=TRUE, signif=NULL, ...)

## S3 method for class 'psych'
summary(object, digits=2, items=FALSE, ...)

Arguments

x  Output from a psych function (e.g., factor.pa, omega, ICLUST, score.items, cluster.cor
object  Output from a psych function
items  items=TRUE (default) does not print the item whole correlations
digits  Number of digits to use in printing
all  if all=TRUE, then the object is declassed and all output from the function is printed
cut  Cluster loadings < cut will not be printed. For the factor analysis functions (fa and factor.pa etc.), cut defaults to 0, for ICLUST to .3, for omega to .2.
sort  Cluster loadings are in sorted order
short  Controls how much to print
lower  For square matrices, just print the lower half of the matrix
signif  If not NULL, a numeric value, show just signif number of leading digits for describe output
...
  More options to pass to summary and print

Details
Most of the psych functions produce too much output. print.psych and summary.psych use generic methods for printing just the highlights. To see what else is available, ask for the structure of the particular object: (str(theobject)).

Alternatively, to get complete output, unclass(theobject) and then print it. This may be done by using the all=TRUE option.

As an added feature, if the promax function is applied to a factanal loadings matrix, the normal output just provides the rotation matrix. print.psych will provide the factor correlations. (Following a suggestion by John Fox and Uli Keller to the R-help list). The alternative is to just use the Promax function directly on the factanal object.
Value

Various psych functions produce copious output. This is a way to summarize the most important parts of the output of the score.items, cluster.scores, and ICLUST functions. See those (score.items, cluster.cor, cluster.loadings, or ICLUST) for details on what is produced.

The signf option is available for the output from describe to adjust the number of digits shown for all columns. This is slightly different from what happens if you specify digits, which rounds all output to the number of digits. print(x,signif=3) will print just the 3 largest digits of x, which will frequently result in scientific notation for any column where that would be appropriate for at least one row.

Note

See score.items, cluster.cor, cluster.loadings, or ICLUST for details on what is printed.

scores <- score.items(keys,psychTools::bfi[1:25])
scores
summary(scores)

Promax

Perform Procustes,bifactor, promax or targeted rotations and return the inter factor angles.

Description

The bifactor rotation implements the rotation introduced by Jennrich and Bentler (2011) by calling GPAforth in the GPArotation package. promax is an oblique rotation function introduced by Hendrickson and White (1964) and implemented in the promax function in the stats package. Unfortunately, promax does not report the inter factor correlations. Promax does. TargetQ does a target rotation with elements that can be missing (NA), or numeric (e.g., 0, 1). It uses the GPArotation package. target.rot does general target rotations to an arbitrary target matrix. The default target rotation is for an independent cluster solution. equamax facilitates the call to GPArotation to do an equamax rotation. Equamax, although available as a specific option within GPArotation is easier to call by name if using equamax. The varimin rotation suggested by Ertl (2013) is implemented by appropriate calls to GPArotation.

Usage

faRotate(loadings,rotate="oblimin",...)
bifactor(L, Tmat=diag(ncol(L)), normalize=FALSE, eps=1e-5, maxit=1000)
biquartimin(L, Tmat=diag(ncol(L)), normalize=FALSE, eps=1e-5, maxit=1000)
TargetQ(L, Tmat=diag(ncol(L)), normalize=FALSE, eps=1e-5, maxit=1000,Target=NULL)
Promax

TargetT(L, Tmat=diag(ncol(L)), normalize=FALSE, eps=1e-5, maxit=1000, Target=NULL)
Promax(x,m=4, normalize=FALSE, pro.m = 4)
Procrustes(L,Target) #adapted from Niels Waler
target.rot(x,keys=NULL)
varimin(L, Tmat = diag(ncol(L)), normalize = FALSE, eps = 1e-05, maxit = 1000)
vQ.bimin(L) #called by bifactor
vQ.targetQ(L,Target=NULL) #called by TargetQ
vQ.varimin(L) #called by varimin
equamax(L, Tmat=diag(ncol(L)), eps=1e-5, maxit=1000)

Arguments

x  A loadings matrix
L  A loadings matrix
loadings  A loadings matrix
rotate  Which rotation should be used?
m  the power to which to raise the varimax loadings (for Promax)
pro.m  the power to which to raise the various loadings in Promax.
keys  An arbitrary target matrix, can be composed of any weights, but probably -1.0, 1 weights. If missing, the target is the independent cluster structure determined by assigning every item to it’s highest loaded factor.
Target  A matrix of values (mainly 0s, some 1s, some NAs) to which the matrix is transformed.
Tmat  An initial rotation matrix
normalize  parameter passed to optimization routine (GPForth in the GPArotation package and Promax)
eps  parameter passed to optimization routine (GPForth in the GPArotation package)
maxit  parameter passed to optimization routine (GPForth in the GPArotation package)
...  Other parameters to pass (e.g. to faRotate) include a Target list or matrix

Details

The two most useful of these functions is probably biquartimin which implements the oblique bi-factor rotation introduced by Jennrich and Bentler (2011). The second is TargetQ which allows for missing NA values in the target. Next best is the orthogonal case, bifactor. None of these seem to be implemented in GPArotation (yet).

TargetT is an orthogonal target rotation function which allows for missing NA values in the target. faRotate is merely a convenient way to call the various GPArotation functions as well as the additional ones added here.

The difference between biquartimin and bifactor is just that the latter is the orthogonal case which is documented in Jennrich and Bentler (2011). It seems as if these two functions are sensitive to the starting values and random restarts (modifying T) might be called for.

bifactor output for the 24 cognitive variable of Holzinger matches that of Jennrich and Bentler as does output for the Chen et al. problem when fm="mle" is used and the Jennrich and Bentler solution is rescaled from covariances to correlations.

Promax is a very direct adaptation of the stats::promax function. The addition is that it will return the interfactor correlations as well as the loadings and rotation matrix.
varimin implements the varimin criterion proposed by Suitbert Ertl (2013). Rather than maximize the varimax criterion, it minimizes it. For a discussion of the benefits of this procedure, consult Ertel (2013).

In addition, these functions will take output from either the factanal, fa or earlier (factor.pa, factor.minres or principal) functions and select just the loadings matrix for analysis.

equamax is just a call to GPArotation’s cFT function (for the Crawford Ferguson family of rotations. TargetQ implements Michael Browne’s algorithm and allows specification of NA values. The Target input is a list (see examples). It is interesting to note how powerful specifying what a factor isn’t works in defining a factor. That is, by specifying the pattern of 0s and letting most other elements be NA, the factor structure is still clearly defined.

The target.rot function is an adaptation of a function of Michael Browne’s to do rotations to arbitrary target matrices. Suggested by Pat Shrout.

The default for target.rot is to rotate to an independent cluster structure (every items is assigned to a group with its highest loading.)

target.rot will not handle targets that have linear dependencies (e.g., a pure bifactor model where there is a g loading and a group factor for all variables).

**Value**

| loadings | Oblique factor loadings |
| rotmat   | The rotation matrix applied to the original loadings to produce the promax solution or the targeted matrix |
| Phi      | The interfactor correlation matrix |

**Note**

Promax is direct adaptation of the stats:promax function following suggestions to the R-help list by Ulrich Keller and John Fox. Further modified to do targeted rotation similar to a function of Michael Browne.

varimin is a direct application of the GPArotation GPForth function modified to do varimin.

**Note**

The Target for TargetT can be a matrix, but for TartetQ must be a list. This seems to be a feature of GPArotation.

#Suitbert Ertel has suggested varimin
fm <- fa(jen,3,rotate="varimin")  #the Ertel varimin
fn <- fa(jen,3,rotate="none")  #just the unrotated factors
#compare them
factor.congruence(list(f3,fb,fq,fm,fn))

psych.misc

Miscellaneous helper functions for the psych package

Description

This is a set of minor, if not trivial, helper functions. lowerCor finds the correlation of x variables and then prints them using lowerMat which is a trivial, but useful, function to round off and print the lower triangle of a matrix. reflect reflects the output of a factor analysis or principal components analysis so that one or more factors is reflected. (Requested by Alexander Weiss.) progressBar prints out ... as a calling routine (e.g., tetrachoric) works through a tedious calculation. shannon finds the Shannon index (H) of diversity or of information. test.all tests all the examples in a package. best.items sorts a factor matrix for absolute values and displays the expanded items names. fa.lookup returns sorted factor analysis output with item labels. cor2 correlates two data.frames (of equal length). levels2numeric and char2numeric convert dataframe columns that are categorical/levels to numeric values.

Usage

psych.misc()
lowerCor(x,digits=2,use="pairwise",method="pearson")
cor2(x, y, digits=2, use="pairwise", method="pearson")
lowerMat(R, digits = 2)
tableF(x, y)
reflect(f, flip=NULL)
progressBar(value, max, label=NULL)
shannon(x, correct=FALSE, base=2)
test.all(pl, package="psych", dependencies
   = c("Depends", "Imports", "LinkingTo"), find=FALSE, skip=NULL)
levels2numeric(x)
char2numeric(x)
isCorrelation(x) # test if an object is a symmetric matrix with diagonals of 1 and
# all values between -1 and 1
isCovariance(x) # test if an object is a symmetric matrix
fromTo(data, from, to=NULL) # convert character names to locations as specified in colnames
# of data
cs(...) # convert a list of text words to character vector
acs(...) # convert a list of text words to a single string

Arguments

R            A rectangular matrix or data frame (probably a correlation matrix)
x            A data matrix or data frame or a vector depending upon the function.
y            A data matrix or data frame or a vector
f            The object returned from either a factor analysis (fa) or a principal components

Details

**lowerCor** prints out the lower off diagonal matrix rounded to digits with column names abbreviated to digits + 3 characters, but also returns the full and unrounded matrix. By default, it uses pairwise deletion of variables. It in turn calls **lowerMat** which does the pretty printing.

It is important to remember to not call **lowerCor** when all you need is **lowerMat**!

**cs** is a direct copy of the Cs function in the Hmisc package by Frank Harrell. Added to psych to avoid the overhead of the Hmisc package.

Value

**tableF** is fast alternative to the table function for creating two way tables of numeric variables. It does not have any of the elegant checks of the table function and thus is much faster. Used in the tetrachoric and polychoric functions to maximize speed.

**lowerCor** Find and prints (using **lowerMat**) the lower diagonal correlation matrix but returns (invisibly) the full correlation matrix found with the use and method parameters. The default values are for pairwise deletion of variables, and to print to 2 decimal places.

**lowerMat** Shows the lower triangle of a matrix, rounded to digits with titles abbreviated to digits + 3.

**progressBar** Display a series of dots as we progress through a slow loop (removed from anything using multicores).

**tableF** (for tableFast) is a cut down version of table that does no error checking, nor returns pretty output, but is significantly faster than table. It will just work on two integer vectors. This is used in polychoric an tetrachoric for about a 50% speed improvement for large problems.

**shannon** finds Shannon’s H index of information. Used for estimating the complexity or diversity of the distribution of responses in a vector or matrix.

\[ H = - \sum p_i \log(p_i) \]

**test.all** allows one to test all the examples in specified package. This allows us to make sure that those examples work when other packages (e.g., psych) are also loaded. This is used when developing revisions to the psych package to make sure the the other packages work. Some packages will not work and/or crash the system (e.g., DeducerPlugInScaling requires Java and even with Java, crashes when loaded, even if psych is not there!). Alternatively, if testing a long list of dependencies, you can skip the first part by specifying them by name.

**cor2** will find and display the correlations between two sets of variables, rounded to digits, using the other options. If x is a list of multiple sets (two or more), then all sets are correlated.

**levels2numeric** converts character data with levels to numeric data. Used in the SAPA analyses where we code some variables, (e.g., gender, education) with character codes to help in the documentation of files, but want to do analyses of correlations with other categorical variables.

**char2numeric** converts character data with levels to numeric data. Used for cases when data from questionnaires include the response categories rather then numeric data. Unless the levels of the data are in meaningful order, the numeric results are not useful. Most useful if doing polychoric analyses.

**fromTo** selects the columns in data from to

temp <- acs("Here is a longish",vector,that,we,\"want to combine\",into,one)
temp
lowerCor(fromTo(sat.act,cs(ACT,SATQ)))
```

### r.test

Tests of significance for correlations

**Description**

Tests the significance of a single correlation, the difference between two independent correlations, the difference between two dependent correlations sharing one variable (Williams’s Test), or the difference between two dependent correlations with different variables (Steiger Tests).
Usage

r.test(n, r12, r34 = NULL, r23 = NULL, r13 = NULL, r14 = NULL, r24 = NULL, n2 = NULL, pooled=TRUE, twotailed = TRUE)

Arguments

n Sample size of first group
r12 Correlation to be tested
r34 Test if this correlation is different from r12, if r23 is specified, but r13 is not, then r34 becomes r13
r23 if ra = r(12) and rb = r(13) then test for differences of dependent correlations given r23
r13 implies ra =r(12) and rb =r(34) test for difference of dependent correlations
r14 implies ra =r(12) and rb =r(34)
r24 ra =r(12) and rb =r(34)
n2 n2 is specified in the case of two independent correlations. n2 defaults to n if if not specified
pooled use pooled estimates of correlations
twotailed should a twotailed or one tailed test be used

Details

Depending upon the input, one of four different tests of correlations is done. 1) For a sample size n, find the t value for a single correlation where

\[ t = \frac{r \sqrt{(n - 2)}}{\sqrt{1 - r^2}} \]

and

\[ se = \sqrt{\frac{1 - r^2}{n - 2}} \]

2) For sample sizes of n and n2 (n2 = n if not specified) find the z of the difference between the z transformed correlations divided by the standard error of the difference of two z scores:

\[ z = \frac{z_1 - z_2}{\sqrt{\frac{1}{n_1 - 3} + \frac{1}{n_2 - 3}}} \]

3) For sample size n, and correlations r12, r13 and r23 test for the difference of two dependent correlations (r12 vs r13).
4) For sample size n, test for the difference between two dependent correlations involving different variables.

Consider the correlations from Steiger (1980), Table 1: Because these all from the same subjects, any tests must be of dependent correlations. For dependent correlations, it is necessary to specify at least 3 correlations (e.g., r12, r13, r23)

<table>
<thead>
<tr>
<th>Variable</th>
<th>M1</th>
<th>F1</th>
<th>V1</th>
<th>M2</th>
<th>F2</th>
<th>V2</th>
</tr>
</thead>
</table>
For clarity, correlations may be specified by value. If specified by location and if doing the test of
dependent correlations, if three correlations are specified, they are assumed to be in the order r12,
r13, r23.

Consider the examples from Steiger:

Case A: where Masculinity at time 1 (M1) correlates with Verbal Ability .5 (r12), femininity at
time 1 (F1) correlates with Verbal ability r13 =.4, and M1 correlates with F1 (r23=.1). Then, given
the correlations: r12 = .4, r13 = .5, and r23 = .1, t = -.89 for n =103, i.e., r.test(n=103, r12=.4,
r13=.5,r23=.1)

Case B: Test whether correlation between two variables (e.g., F and V) is the same over time (e.g.
F1V1 = F2V2)

r.test(n = 103, r12 = 0.5, r34 = 0.6, r23 = 0.5, r13 = 0.7, r14 = 0.5, r24 = 0.8)

Value

test Label of test done
z z value for tests 2 or 4
t t value for tests 1 and 3
p probability value of z or t

Note

Steiger specifically rejects using the Hotelling T test to test the difference between correlated cor-
relations. Instead, he recommends Williams’ test. (See also Dunn and Clark, 1971). These tests
follow Steiger’s advice. The test of two independent correlations is just a z test of the difference of
the Fisher’s z transformed correlations divided by the standard error of the difference. (See Cohen
et al, p 49).

One of the beautiful features of R is what works on single value works on vectors and matrices.
Thus, r.test can be used to test the pairwise diference of all the elements of a correlation matrix. See
the last example.

By default, the probabilities are reported to 2 decimal places. This will, of course, sometimes lead
to statements such as p < .1 when in fact p < .1001 or even more precisely p < .1000759. To achieve
the higher precision, use a print statement with the preferred number of digits. See the next to last
set of examples (courtesy of Julia Rohrer).

Examples

```r	n <- 30
r <- seq(0,.9,.1)
rc <- matrix(r.con(r,n),ncol=2)
test <- r.test(n,r)
r.rc <- data.frame(r=r,z=fisherz(r),lower=rc[,1],upper=rc[,2],t=test$t,p=test$p)
round(r.rc,2)

r.test(50,r)
r.test(30,.4,.6) #test the difference between two independent correlations
r.test(103,.4,.5,.1) #Steiger case A of dependent correlations
r.test(n=103,r12=.4,r13=.5,r23=.1)
# for complicated tests, it is probably better to specify correlations by name
r.test(n=103,r12=.5,r23=.6,r13=.7,r23=.5,r14=.5,r24=.8) # steiger Case B

## By default, the precision of p values is 2 decimals
# Consider three different precisions shown by varying the requested number of digits
r12 = 0.693458895410494
r23 = 0.988475791500198
r13 = 0.695966022434845
print(r.test(n = 5105 , r12 = r12 , r23 = r23 , r13 = r13 )) # probability < 0.1
print(r.test(n = 5105 , r12 = r12, r23 = r23 , r13 = r13 ),digits=4) # p < 0.1001
print(r.test(n = 5105 , r12 = r12, r23 = r23 , r13 = r13 ),digits=8) # p < 0.1000759

# an example of how to compare the elements of two matrices
R1 <- lowerCor(psychTools::bfi[1:200,1:5]) # find one set of Correlations
R2 <- lowerCor(psychTools::bfi[201:400,1:5]) # and now another set sampled
# from the same population

test <- r.test(n=200, r12 = R1, r34 = R2)
round(lowerUpper(R1,R2,diff=TRUE),digits=2) # show the differences between correlations
# lowerMat(test$p) # show the p values of the difference between the two matrices
adjusted <- p.adjust(test$p[upper.tri(test$p)])
both <- test$p
both[upper.tri(both)] <- adjusted
round(both,digits=2) # The lower off diagonal are the raw ps, the upper the adjusted ps
```

Correct correlations for restriction of range. (Thorndike Case 2)

Description

In applied settings, it is typical to find a correlation between a predictor and some criterion. Unfortunately, if the predictor is used to choose the subjects, the range of the predictor is seriously reduced. This restricts the observed correlation to be less than would be observed in the full range of the predictor. A correction for this problem is well known as Thorndike Case 2:

Let $R$ the unrestricted correlation, $r$ the restricted correlation, $S$ the unrestricted standard deviation, $s$ the restricted standard deviation, then

$$R = \frac{rS/s}{\sqrt{1-r^2 + r^2(S^2/s^2)}}.$$  

Several other cases of restriction were also considered by Thorndike and are implemented in `rangeCorrection`.

Usage

```r
rangeCorrection(r, sdu, sdr, sdxu=NULL, sdxr=NULL, case=2)
```

Arguments

- `r` The observed correlation
- `sdu` The unrestricted standard deviation
- `sdr` The restricted standard deviation
- `sdxu` Unrestricted standard deviation for case 4
- `sdxr` Restricted standard deviation for case 4
- `case` Which of the four Thurstone/Stauffer cases to use

Details

When participants in a study are selected on one variable, that will reduce the variance of that variable and the resulting correlation. Thorndike (1949) considered four cases of range restriction. Others have continued this discussion but have changed the case numbers. Can be used to find correlations in a restricted sample as well as the unrestricted sample. Not the same as the correction to reliability for restriction of range.

Value

The corrected correlation.

rescale Function to convert scores to "conventional " metrics

Description
Psychologists frequently report data in terms of transformed scales such as “IQ” (mean=100, sd=15, “SAT/GRE” (mean=500, sd=100), “ACT” (mean=18, sd=6), “T-scores” (mean=50, sd=10), or “Sta- nines” (mean=5, sd=2). The rescale function converts the data to standard scores and then rescales to the specified mean(s) and standard deviation(s).

Usage
rescale(x, mean = 100, sd = 15,df=TRUE)

Arguments
x A matrix or data frame
mean Desired mean of the rescaled scores- may be a vector
sd Desired standard deviation of the rescaled scores
df if TRUE, returns a data frame, otherwise a matrix

Value
A data.frame (default) or matrix of rescaled scores.

Author(s)
William Revelle

See Also scale

Examples
T <- rescale(attitude,50,10) #all put on same scale
describe(T)
T1 <- rescale(attitude,seq(0,300,50),seq(10,70,10)) #different means and sigmas
describe(T1)
Residuals in the various psych functions are extracted and then may be "pretty" printed.

## S3 method for class 'psych'
residuals(object, diag = TRUE, ...)
## S3 method for class 'psych'
resid(object, diag = TRUE, ...)

### Arguments
- **object**: The object returned by a psych function.
- **diag**: if FALSE, then convert the diagonal of the residuals to NA
- **...**: Other parameters to be passed to residual (ignored but required by the generic function)

### Details
Currently implemented for `fa`, `principal`, `omega`, `irt.fa`, and `fa.extension`.

### Value
- residuals: a matrix of residual estimates

### Examples
```r
f3 <- fa(Thurstone, 3)
residuals(f3)
sum(residuals(f3)^2)  # include diagonal
sum(residuals(f3, diag = FALSE)^2, na.rm = TRUE)  # drop diagonal
```
reverse.code  

Reverse the coding of selected items prior to scale analysis

Description

Some IRT functions require all items to be coded in the same direction. Some data sets have items that need to be reverse coded (e.g., 6 -> 1, 1 -> 6). reverse.code will flip items based upon a keys vector of 1s and -1s. Reversed items are subtracted from the item max + item min. These may be specified or may be calculated.

Usage

reverse.code(keys, items, mini = NULL, maxi = NULL)

Arguments

keys  A vector of 1s and -1s. -1 implies reverse the item
items  A data set of items
mini  if NULL, the empirical minimum for each item. Otherwise, a vector of minima
maxi  if NULL, the empirical maximum for each item. Otherwise, a vector of maxima

Details

Not a very complicated function, but useful in the case that items need to be reversed prior to using IRT functions from the ltm or eRM packages. Most psych functions do not require reversing prior to analysis, but will do so within the function.

Value

The corrected items.

Examples

original <- matrix(sample(6,50,replace=TRUE),10,5)
keys <- c(1,1,-1,-1,1) #reverse the 3rd and 4th items
new <- reverse.code(keys,original,mini=rep(1,5),maxi=rep(6,5))
original[1:3,]
new[1:3,]

sat.act  3 Measures of ability: SATV, SATQ, ACT

Description

Self reported scores on the SAT Verbal, SAT Quantitative and ACT were collected as part of the Synthetic Aperture Personality Assessment (SAPA) web based personality assessment project. Age, gender, and education are also reported. The data from 700 subjects are included here as a demonstration set for correlation and analysis.
Usage

data(sat.act)

Format

A data frame with 700 observations on the following 6 variables.

- gender: males = 1, females = 2
- education: self reported education (1 = high school ... 5 = graduate work)
- age
- ACT: ACT composite scores may range from 1 - 36. National norms have a mean of 20.
- SATV: SAT Verbal scores may range from 200 - 800.
- SATQ: SAT Quantitative scores may range from 200 - 800

Details

These items were collected as part of the SAPA project (https://sapa-project.org) to develop online measures of ability (Revelle, Wilt and Rosenthal, 2009). The score means are higher than national norms suggesting both self selection for people taking online personality and ability tests and a self reporting bias in scores.

See also the iq.items data set.

scaling.fits

Test the adequacy of simple choice, logistic, or Thurstonian scaling.

Description

Given a matrix of choices and a vector of scale values, how well do the scale values capture the choices? That is, what is size of the squared residuals given the model versus the size of the squared choice values?

Usage

scaling.fits(model, data, test = "logit", digits = 2, rowwise = TRUE)
**scatterHist**

**Arguments**

- **model**: A vector of scale values
- **data**: A matrix or dataframe of choice frequencies
- **test**: "choice", "logistic", "normal"
- **digits**: Precision of answer
- **rowwise**: Are the choices ordered by column over row (TRUE) or row over column (FALSE)

**Details**

How well does a model fit the data is the classic problem of all of statistics. One fit statistic for scaling is the just the size of the residual matrix compared to the original estimates.

**Value**

- **GF**: Goodness of fit of the model
- **original**: Sum of squares for original data
- **resid**: Sum of squares for residuals given the data and the model
- **residual**: Residual matrix

**Note**

Mainly for demonstration purposes for a course on psychometrics

**scatterHist**

*Draw a scatter plot with associated X and Y histograms, densities and correlation*

**Description**

Draw a X Y scatter plot with associated X and Y histograms with estimated densities. Partly a demonstration of the use of layout. Also includes lowess smooth or linear model slope, as well as correlation. Adapted from addicted to R example 78 with further modifications suggested by Jared Smith.
Usage

scatterHist(x,y=NULL,smooth=TRUE,correl=TRUE,density=TRUE,ellipse=TRUE,
digits=2,method,cex.cor=1, title="Scatter plot + histograms", xlab=NULL,ylab=NULL,
smoother=FALSE,nrpoints=0, xlab.hist=NULL,ylab.hist=NULL,grid=FALSE, xlim=NULL,
ylim=NULL, x.breaks=11,y.breaks=11, x.space=0, y.space=0 ,freq=TRUE, x.axes=TRUE,
y.axes=TRUE,size=c(1,2),...)

scatter.hist(x,y=NULL,smooth=TRUE,correl=TRUE, density=TRUE, ellipse=TRUE,
digits=2, method,cex.cor=1, title="Scatter plot + histograms",
xlab=NULL,ylab=NULL,smoother=FALSE, nrpoints=0, xlab.hist=NULL, ylab.hist=NULL,
grid=FALSE, xlim=NULL,ylim=NULL,x.breaks=11,y.breaks=11, x.space=0,y.space=0,
freq=TRUE,x.axes=TRUE,y.axes=TRUE,size=c(1,2),...)

Arguments

x
The X vector, or the first column of a data.frame or matrix.
y
The Y vector, or the first column of X
smooth
if TRUE, then add a loess smooth to the plot
ab
if TRUE, then show the best fitting linear fit
correl
TRUE: Show the correlation
density
TRUE: Show the estimated densities
ellipse
TRUE: draw 1 and 2 sigma ellipses and smooth
digits
How many digits to use if showing the correlation
method
Which method to use for correlation ("pearson","spearman","kendall") defaults to "pearson"
smoother
if TRUE, use smoothScatter instead of plot. Nice for large N.
nrpoints
If using smoothScatter, show nrpoints as dots. Defaults to 0
grid
If TRUE, show a grid for the scatter plot.
cex.cor
Adjustment for the size of the correlation
xlab
Label for the x axis
ylab
Label for the y axis
xlim
Allow specification for limits of x axis, although this seems to just work for the scatter plots.
ylim
Allow specification for limits of y axis
x.breaks
Number of breaks to suggest to the x axis histogram.
y.breaks
Number of breaks to suggest to the y axis histogram.
x.space
space between bars
y.space
Space between y bars
freq
Show frequency counts, otherwise show density counts
x.axes
Show the x axis for the x histogram
y.axes
Show the y axis for the y histogram
size
The sizes of the ellipses (in sd units). Defaults to 1,2
xlab.hist
Not currently available
ylab.hist
Label for y axis histogram. Not currently available.
title
An optional title
...
Other parameters for graphics
Details

Just a straightforward application of layout and barplot, with some tricks taken from `pairs.panels`. The various options allow for correlation ellipses (1 and 2 sigma from the mean), lowess smooths, linear fits, density curves on the histograms, and the value of the correlation. `ellipse = TRUE` implies `smooth = TRUE`. The `grid` option provides a background grid to the scatterplot.

Note

Adapted from Addicted to R example 78. Modified following some nice suggestions from Jared Smith.

`pairs.panels` for multiple plots, `multi.hist` for multiple histograms.

Examples

```r
data(sat.act)
with(sat.act, scatter.hist(SATV, SATQ))
# or for something a bit more splashy
scatter.hist(sat.act[5:6], pch=(19 + sat.act$gender), col=c("blue", "red")[sat.act$gender], grid=TRUE)
```

| Schmid | 12 variables created by Schmid and Leiman to show the Schmid-Leiman Transformation |

Description

John Schmid and John M. Leiman (1957) discuss how to transform a hierarchical factor structure to a bifactor structure. Schmid contains the example 12 x 12 correlation matrix. `schmid.leiman` is a 12 x 12 correlation matrix with communalities on the diagonal. This can be used to show the effect of correcting for attenuation. Two additional data sets are taken from Chen et al. (2006).

Usage

```r
data(Schmid)
```

Details

Two artificial correlation matrices from Schmid and Leiman (1957). One real and one artificial covariance matrices from Chen et al. (2006).

- Schmid: a 12 x 12 artificial correlation matrix created to show the Schmid-Leiman transformation.
- `schmid.leiman`: A 12 x 12 matrix with communalities on the diagonal. Treating this as a covariance matrix shows the 6 x 6 factor solution
• Chen: An 18 x 18 covariance matrix of health related quality of life items from Chen et al. (2006). Number of observations = 403. The first item is a measure of the quality of life. The remaining 17 items form four subfactors: The items are (a) Cognition subscale: “Have difficulty reasoning and solving problems?” “React slowly to things that were said or done?” “Become confused and start several actions at a time?” “Forget where you put things or appointments?” “Have difficulty concentrating?” (b) Vitality subscale: “Feel tired?” “Have enough energy to do the things you want?” (R) “Feel worn out?” ; “Feel full of pep?” (R). (c) Mental health subscale: “Feel calm and peaceful?”(R) “Feel downhearted and blue?” ; “Feel very happy”(R) ; “Feel very nervous?” ; “Feel so down in the dumps nothing could cheer you up?” (d) Disease worry subscale: “Were you afraid because of your health?”; “Were you frustrated about your health?”; “Was your health a worry in your life?”.

• West: A 16 x 16 artificial covariance matrix from Chen et al. (2006).

Examples

data(Schmid)
cor.plot(Schmid,TRUE)
print(fa(Schmid,6,rotate="oblimin"),cut=0) #shows an oblique solution
round(cov2cor(schmid.leiman),2)
cor.plot(cov2cor(West),TRUE)

---

**schmid**

*Apply the Schmid Leiman transformation to a correlation matrix*

**Description**

One way to find omega is to do a factor analysis of the original data set, rotate the factors obliquely, do a Schmid Leiman transformation, and then find omega. Here is the code for Schmid Leiman. The S-L transform takes a factor or PC solution, transforms it to an oblique solution, factors the oblique solution to find a higher order (g) factor, and then residualizes g out of the the group factors.

**Usage**

```
schmid(model, nfactors = 3, fm = "minres",digits=2,rotate="oblimin", n.obs=NA,option="equal",Phi=NULL,covar=FALSE,...)
```
Arguments

model
A correlation matrix

nfactors
Number of factors to extract

fm
the default is to do minres. fm="pa" for principal axes, fm="pc" for principal components, fm = "minres" for minimum residual (OLS), pc="ml" for maximum likelihood

digits
if digits not equal NULL, rounds to digits

rotate
The default, oblimin, produces somewhat more correlated factors than the alternative, simplimax. Other options include Promax (not Kaiser normalized) or promax (Promax with Kaiser normalization). See fa for possible oblique rotations.

n.obs
Number of observations, used to find fit statistics if specified. Will be calculated if input is raw data

option
When asking for just two group factors, option can be for "equal", "first" or "second"

Phi
If Phi is specified, then the analysis is done on a pattern matrix with the associated factor intercorrelation (Phi) matrix. This allows for reanalysis of published results

covar
Defaults to FALSE and finds correlations. If set to TRUE, then do the calculations on the unstandardized variables.

... Allows additional parameters to be passed to the factoring routines

Details

Schmid Leiman orthogonalizations are typical in the ability domain, but are not seen as often in the non-cognitive personality domain. S-L is one way of finding the loadings of items on the general factor for estimating omega.

A typical example would be in the study of anxiety and depression. A general neuroticism factor (g) accounts for much of the variance, but smaller group factors of tense anxiety, panic disorder, depression, etc. also need to be considered.

An alternative model is to consider hierarchical cluster analysis techniques such as ICLUST. Requires the GPArotation package.

Although 3 factors are the minimum number necessary to define the solution uniquely, it is occasionally useful to allow for a two factor solution. There are three possible options for this condition: setting the general factor loadings between the two lower order factors to be "equal" which will be the sqrt(oblique correlations between the factors) or to "first" or "second" in which case the general factor is equated with either the first or second group factor. A message is issued suggesting that the model is not really well defined.

A diagnostic tool for testing the appropriateness of a hierarchical model is p2 which is the percent of the common variance for each variable that is general factor variance. In general, p2 should not have much variance.

Value

sl
loadings on g + nfactors group factors, communalities, uniqueness, percent of g2 of h2

Orthog
original orthogonal factor loadings
score.alpha

Score scales and find Cronbach's alpha as well as associated statistics

Description

Given a matrix or data.frame of k keys for m items (-1, 0, 1), and a matrix or data.frame of items scores for m items and n people, find the sum scores or average scores for each person and each scale. In addition, report Cronbach’s alpha, the average r, the scale intercorrelations, and the item by scale correlations. (Superseded by score.items).

Usage

```r
score.alpha(keys, items, labels = NULL, totals=TRUE,digits = 2) #deprecated
```

Arguments

<table>
<thead>
<tr>
<th>keys</th>
<th>A matrix or dataframe of -1, 0, or 1 weights for each item on each scale</th>
</tr>
</thead>
<tbody>
<tr>
<td>items</td>
<td>Data frame or matrix of raw item scores</td>
</tr>
<tr>
<td>labels</td>
<td>column names for the resulting scales</td>
</tr>
<tr>
<td>totals</td>
<td>Find sum scores (default) or average score</td>
</tr>
<tr>
<td>digits</td>
<td>Number of digits for answer (default =2)</td>
</tr>
</tbody>
</table>
Details

This function has been replaced with `score.items` (for multiple scales) and `alpha` for single scales.

The process of finding sum or average scores for a set of scales given a larger set of items is a typical problem in psychometric research. Although the structure of scales can be determined from the item intercorrelations, to find scale means, variances, and do further analyses, it is typical to find the sum or the average scale score.

Various estimates of scale reliability include “Cronbach’s alpha”, and the average interitem correlation. For $k =$ number of items in a scale, and $av.r =$ average correlation between items in the scale, $\alpha = \frac{k \times av.r}{1 + (k-1)\times av.r}$. Thus, $\alpha$ is an increasing function of test length as well as the test homeogeneity.

Alpha is a poor estimate of the general factor saturation of a test (see Zinbarg et al., 2005) for it can seriously overestimate the size of a general factor, and a better but not perfect estimate of total test reliability because it underestimates total reliability. None the less, it is a useful statistic to report.

Value

- `scores`: Sum or average scores for each subject on the $k$ scales
- `alpha`: Cronbach’s coefficient alpha. A simple (but non-optimal) measure of the internal consistency of a test. See also beta and omega.
- `av.r`: The average correlation within a scale, also known as alpha 1 is a useful index of the internal consistency of a domain.
- `n.items`: Number of items on each scale
- `cor`: The intercorrelation of all the scales
- `item.cor`: The correlation of each item with each scale. Because this is not corrected for item overlap, it will overestimate the amount that an item correlates with the other items in a scale.

Examples

```r
y <- attitude  #from the datasets package
t keys <- matrix(c(rep(1,7),rep(1,4),rep(0,7),rep(-1,3)),ncol=3)
labels <- c("first","second","third")
x <- score.alpha(keys,y,labels)  #deprecated
```
Score multiple choice items and provide basic test statistics

Description

Ability tests are typically multiple choice with one right answer. score.multiple.choice takes a scoring key and a data matrix (or data.frame) and finds total or average number right for each participant. Basic test statistics (alpha, average r, item means, item-whole correlations) are also reported.

Usage

score.multiple.choice(key, data, score = TRUE, totals = FALSE, ilabels = NULL, missing = TRUE, impute = "median", digits = 2, short=TRUE, skew=FALSE)

Arguments

key A vector of the correct item alternatives
data a matrix or data frame of items to be scored.
score score=FALSE, just convert to right (1) or wrong (0).
score=TRUE, find the totals or average scores and do item analysis
totals total=FALSE: find the average number correct
total=TRUE: find the total number correct
ilabels item labels
missing missing=TRUE: missing values are replaced with means or medians
missing=FALSE: missing values are not scored
impute impute="median": replace missing items with the median score
impute="mean": replace missing values with the item mean
digits How many digits of output
short short=TRUE, just report the item statistics.
short=FALSE, report item statistics and subject scores as well
skew Should the skews and kurtosis of the raw data be reported? Defaults to FALSE because what is the meaning of skew for a multiple choice item?

Details

Basically combines score.items with a conversion from multiple choice to right/wrong. The item-whole correlation is inflated because of item overlap.

The example data set is taken from the Synthetic Aperture Personality Assessment personality and ability test at https://sapa-project.org.

Value

scores Subject scores on one scale
missing Number of missing items for each subject
item.stats scoring key, response frequencies, item whole correlations, n subjects scored, mean, sd, skew, kurtosis and se for each item
alpha Cronbach’s coefficient alpha
av.r Average interitem correlation
**scoreIrt**

Find Item Response Theory (IRT) based scores for dichotomous or polytomous items

**Description**

`irt.fa` finds Item Response Theory (IRT) parameters through factor analysis of the tetrachoric or polychoric correlations of dichotomous or polytomous items. `scoreIrt` uses these parameter estimates of discrimination and location to find IRT based scores for the responses. As many factors as found for the correlation matrix will be scored. `scoreIrt.2pl` will score lists of scales.

**Usage**

```r
scoreIrt(stats=NULL, items, keys=NULL, cut = 0.3, bounds=c(-4,4), mod="logistic")
scoreIrt.1pl(keys.list,items,correct=.5,messages=FALSE,cut=.3,bounds=c(-4,4),
             mod="logistic") #Rasch like scaling
scoreIrt.2pl(itemLists,items,correct=.5,messages=FALSE,cut=.3,bounds=c(-4,4),
             mod="logistic") #2 pl scoring
#the next is an alias for scoreIrt both of which are wrappers for
# score.irt.2 and score.irt.poly
score.irt(stats=NULL, items, keys=NULL, cut = 0.3, bounds=c(-4,4), mod="logistic")
#the higher order call just calls one of the next two
#for dichotomous items
score.irt.2(stats, items,keys=NULL, cut = 0.3,bounds=c(-4,4),mod="logistic")
#for polytomous items
score.irt.poly(stats, items, keys=NULL, cut = 0.3,bounds=c(-4,4),mod="logistic")
#to create irt like statistics for plotting
irt.stats.like(items,stats,keys=scoreIrt, cut=.3)
made.irt.stats(diffticulty,discrimination)

irt.tau(x) #find the tau values for the x object
irt.se(stats,scores=0,D=1.702)
```

**Examples**

```r
data(psychTools::iqitems)
q.keys <- c(4,4,4, 6,6,3,4,4, 5,2,2,4, 3,2,6,7)
score.multiple.choice(iq.keys,psychTools::iqitems)
#just convert the items to true or false
iq.tf <- score.multiple.choice(iq.keys,psychTools::iqitems,score=FALSE)
describe(iq.tf) #compare to previous results
```
Arguments

**stats**
Output from irt.fa is used for parameter estimates of location and discrimination. Stats may also be the output from a normal factor analysis (fa). If stats is a data.frame of discrimination and thresholds from some other data set, these values will be used. See the last example.

**items**
The raw data, may be either dichotomous or polytomous.

**itemLists**
a list of items to be factored and scored for each scale, can be a keys.list as used in scoreItems or scoreIrt.1pl

**keys.list**
A list of items to be scored with keying direction (see example)

**keys**
A keys matrix of which items should be scored for each factor

**cut**
Only items with discrimination values > cut will be used for scoring.

**x**
The raw data to be used to find the tau parameter in irt.tau

**bounds**
The lower and upper estimates for the fitting function

**mod**
Should a logistic or normal model be used in estimating the scores?

**correct**
What value should be used for continuity correction when finding the tetrachoric or polychoric correlations when using irt.fa

**messages**
Should messages be suppressed when running multiple scales?

**scores**
A single score or a vector of scores to find standard errors

**D**
The scaling function for the test information statistic used in irt.se

**difficulty**
The difficulties for each item in a polytomous scoring

**discrimination**
The item discrimin

Details

Although there are more elegant ways of finding subject scores given a set of item locations (difficulties) and discriminations, simply finding that value of theta $\theta$ that best fits the equation $P(x | \theta) = 1 / (1 + \exp(\beta(\delta - \theta)))$ for a score vector X, and location $\delta$ and discrimination $\beta$ provides more information than just total scores. With complete data, total scores and irt estimates are almost perfectly correlated. However, the irt estimates provide much more information in the case of missing data.

The bounds parameter sets the lower and upper limits to the estimate. This is relevant for the case of a subject who gives just the lowest score on every item, or just the top score on every item. Formerly (prior to 1.6.12) this was done by estimating these taila scores by finding the probability of missing every item taken, converting this to a quantile score based upon the normal distribution, and then assigning a z value equivalent to 1/2 of that quantile. Similarly, if a person gets all the items they take correct, their score is defined as the quantile of the z equivalent to the probability of getting all of the items correct, and then moving up the distribution half way. If these estimates exceed either the upper or lower bounds, they are adjusted to those boundaries.

As of 1.6.9, the procedure is very different. We now assume that all items are bounded with one passed item that is easier than all items given, and one failed item that is harder than any item given. This produces much cleaner results.

There are several more elegant packages in R that provide Full Information Maximum Likelihood IRT based estimates. In particular, the MIRT package seems especially good. The ltm package gives equivalent estimates to MIRT for dichotomous data but produces unstable estimates for polytomous data and should be avoided.

Although the scoreIrt estimates are are not FIML based they seem to correlated with the MIRT estimates with values exceeding .99. Indeed, based upon very limited simulations there are some small
hints that the solutions match the true score estimates slightly better than do the MIRT estimates. scoreIrt seems to do a good job of recovering the basic structure.

If trying to use item parameters from a different data set (e.g. some standardization sample), specify the stats as a data frame with the first column representing the item discriminations, and the next columns the item difficulties. See the last example.

The two wrapper functions scoreIrt.1pl and scoreIrt.2pl are very fast and are meant for scoring one or many scales at a time with a one factor model (scoreIrt.2pl) or just Rasch like scoring. Just specify the scoring direction for a number of scales (scoreIrt.1pl) or just items to score for a number of scales scoreIrt.2pl. scoreIrt.2pl will then apply irt.fa to the items for each scale separately, and then find the 2pl scores.

The keys.list is a list of items to score for each scale. Preceding the item name with a negative sign will reverse score that item (relevant for scoreIrt.1pl. Alternatively, a keys matrix can be created using make.keys. The keys matrix is a matrix of 1s, 0s, and -1s reflecting whether an item should be scored or not scored for a particular factor. See scoreItems or make.keys for details. The default case is to score all items with absolute discriminations > cut.

If one wants to score scales taking advantage of differences in item location but not do a full IRT analysis, then find the item difficulties from the raw data using irt.tau or combine this information with a scoring keys matrix (see scoreItems and make.keys and create quasi-IRT statistics using irt.stats.like. This is the equivalent of doing a quasi-Rasch model, in that all items are assumed to be equally discriminating. In this case, tau values may be found first (using irt.tau or just found before doing the scoring. This is all done for you inside of scoreIrt.1pl.

Such irt based scores are particularly useful if finding scales based upon massively missing data (e.g., the SAPA data sets). Even without doing the full irt analysis, we can take into account different item difficulties.

David Condon has added a very nice function to do 2PL analysis for a number of scales at one time. scoreIrt.2pl takes the raw data file and a list of items to score for each of multiple scales. These are then factored (currently just one factor for each scale) and the loadings and difficulties are used for scoring.

There are conventionally two different metrics and models that are used. The logistic metric and model and the normal metric and model. These are chosen using the mod parameter. irt.se finds the standard errors for scores with a particular value. These are based upon the information curves calculated by irt.fa and are not based upon the particular score of a particular subject.

Value

scores A data frame of theta estimates, total scores based upon raw sums, and estimates of fit.

tau Returned by irt.tau: A data frame of the tau values for an object of dichotomous or polytomous items. Found without bothering to find the correlations.

Note

It is very important to note that when using irt.fa to find the discriminations, to set the sort option to be FALSE. This is now the default. Otherwise, the discriminations will not match the item order.

Always under development. Suggestions for improvement are most appreciated.

scoreIrt is just a wrapper to score.irt.poly and score.irt.2. The previous version had score.irt which is now deprecated as I try to move to camelCase.

scoreIrt.2pl is a wrapper for irt.fa and scoreIrt. It was originally developed by David Condon.

scoreItems

Score item composite scales and find Cronbach's alpha, Guttman lambda 6 and item whole correlations

Description

Given a data.frame or matrix of n items and N observations and a list of the direction to score them (a keys.list with k keys) find the sum scores or average scores for each person and each scale. In addition, report Cronbach's alpha, Guttman's Lambda 6, the average r, the scale intercorrelations, and the item by scale correlations (raw and corrected for item overlap). Replace missing values with the item median or mean if desired. Items may be keyed 1 (score it), -1 (reverse score it), or 0 (do not score it). Negatively keyed items will be reverse scored. Although prior versions used a keys matrix, it is now recommended to just use a list of scoring keys. See make.keys for a convenient way to make the keys file. If the input is a square matrix, then it is assumed that the input is a covariance or correlation matrix and scores are not found, but the item statistics are reported. (Similar functionality to cluster.cor). response.frequencies reports the frequency of item endorsements for each response category for polytomous or multiple choice items. scoreFast and scoreVeryFast just find sums/mean scores and do not report reliabilities. Much faster for large data sets.

Usage

scoreItems(keys, items, totals = FALSE, ilabels = NULL, missing=TRUE, impute="median", delete=TRUE, min = NULL, max = NULL, digits = 2, n.obs=NULL, select=TRUE)
score.items(keys, items, totals = FALSE, ilabels = NULL, missing=TRUE, impute="median", delete=TRUE, min = NULL, max = NULL, digits = 2, select=TRUE)
scoreFast(keys, items, totals = FALSE, ilabels = NULL, missing=TRUE, impute="none", delete=TRUE, min = NULL, max = NULL, count.responses=FALSE, digits = 2)
scoreVeryFast(keys,items,totals=FALSE, min=NULL,max=NULL,count.responses=FALSE)
response.frequencies(items,max=10,uniqueitems=NULL)

Arguments

keys A list of scoring keys or a matrix or dataframe of -1, 0, or 1 weights for each item on each scale which may be created by hand, or by using make.keys. Just using a list of scoring keys (see example) is probably more convenient.

items Matrix or dataframe of raw item scores

totals if TRUE find total scores, if FALSE (default), find average scores

ilabels a vector of item labels.

missing missing = TRUE is the normal case and data are imputed according to the impute option. missing=FALSE, only complete cases are scored.

impute impute="median" replaces missing values with the item medians, impute = "mean" replaces values with the mean response. impute="none" the subject's scores are based upon the average of the keyed, but non missing scores. impute = "none" is probably more appropriate for a large number of missing cases (e.g., SAPA data).
delete

if delete=TRUE, automatically delete items with no variance (and issue a warning)

min

May be specified as minimum item score allowed, else will be calculated from data. min and max should be specified if items differ in their possible minima or maxima. See notes for details.

max

May be specified as maximum item score allowed, else will be calculated from data. Alternatively, in response frequencies, it is maximum number of alternative responses to count.

uniqueitems

If specified, the set of possible unique response categories

digits

Number of digits to report for mean scores

n.obs

If scoring from a correlation matrix, specify the number of subjects allows for the calculation of the confidence intervals for alpha.

select

By default, just find the statistics of those items that are included in scoring keys. This allows scoring of data sets that have bad data for some items that are not included in the scoring keys. This also speeds up the scoring of small subsets of item from larger data sets.

count.responses

If TRUE, report the number of items/scale answered for each subject.

Details

The process of finding sum or average scores for a set of scales given a larger set of items is a typical problem in applied psychometrics and in psychometric research. Although the structure of scales can be determined from the item intercorrelations, to find scale means, variances, and do further analyses, it is typical to find scores based upon the sum or the average item score. For some strange reason, personality scale scores are typically given as totals, but attitude scores as averages. The default for scoreItems is the average as it would seem to make more sense to report scale scores in the metric of the item.

When scoring more than one scale, it is convenient to have a list of the items on each scale and the direction to score the items. This may be converted to a keys.matrix using make.keys or may be entered as a keys.list directly.

Various estimates of scale reliability include “Cronbach’s alpha”, Guttman’s Lambda 6, and the average interitem correlation. For k = number of items in a scale, and av.r = average correlation between items in the scale, alpha = k * av.r/(1+ (k-1)*av.r). Thus, alpha is an increasing function of test length as well as the test homeogeneity.

Surprisingly, more than a century after Spearman (1904) introduced the concept of reliability to psychologists, there are still multiple approaches for measuring it. Although very popular, Cronbach’s α (1951) underestimates the reliability of a test and over estimates the first factor saturation. α (Cronbach, 1951) is the same as Guttman’s λ₃ (Guttman, 1945) and may be found by

\[ \lambda_3 = \frac{n}{n-1} \left(1 - \frac{tr(\bar{V})_x}{V_x}\right) = \frac{n}{n-1} \frac{V_x - tr(\bar{V})}{V_x} = \alpha \]

Perhaps because it is so easy to calculate and is available in most commercial programs, alpha is without doubt the most frequently reported measure of internal consistency reliability. Alpha is the mean of all possible split half reliabilities (corrected for test length). For a unifactorial test, it is a reasonable estimate of the first factor saturation, although if the test has any microstructure (i.e., if it is “lumpy”) coefficients β (Revelle, 1979; see ICLUST) and ωₜ (see omega) (McDonald, 1999; Revelle and Zinbarg, 2009) are more appropriate estimates of the general factor saturation. ωₜ (see omega) is a better estimate of the reliability of the total test.
Guttman’s Lambda 6 (G6) considers the amount of variance in each item that can be accounted for by the linear regression of all of the other items (the squared multiple correlation or smc), or more precisely, the variance of the errors, $e^2_j$, and is

$$\lambda_6 = 1 - \frac{\sum e^2_j}{V_x} = 1 - \frac{\sum(1 - r^2_{smc})}{V_x}. $$

The squared multiple correlation is a lower bound for the item communality and as the number of items increases, becomes a better estimate.

G6 is also sensitive to lumpyness in the test and should not be taken as a measure of unifactorial structure. For lumpy tests, it will be greater than alpha. For tests with equal item loadings, alpha > G6, but if the loadings are unequal or if there is a general factor, G6 > alpha. Although it is normal when scoring just a single scale to calculate G6 from just those items within the scale, logically it is appropriate to estimate an item reliability from all items available. This is done here and is labeled as G6* to identify the subtle difference.

Alpha and G6* are both positive functions of the number of items in a test as well as the average intercorrelation of the items in the test. When calculated from the item variances and total test variance, as is done here, raw alpha is sensitive to differences in the item variances. Standardized alpha is based upon the correlations rather than the covariances. alpha is a generalization of an earlier estimate of reliability for tests with dichotomous items developed by Kuder and Richardson, known as KR20, and a shortcut approximation, KR21. (See Revelle, in prep; Revelle and Condon, in press.).

A useful index is the ratio of reliable variance to unreliable variance and is known as the Signal/Noise ratio. This is just

$$\frac{s}{n} = \frac{nF}{1 - nF} $$

(Cronbach and Gleser, 1964; Revelle and Condon (in press)).

Standard errors for unstandardized alpha are reported using the formula from Duhacheck and Jacobucci (2005).

More complete reliability analyses of a single scale can be done using the omega function which finds $\omega_h$ and $\omega_t$ based upon a hierarchical factor analysis. Alternative estimates of the Greatest Lower Bound for the reliability are found in the guttman function.

Alpha is a poor estimate of the general factor saturation of a test (see Revelle and Zinbarg, 2009; Zinbarg et al., 2005) for it can seriously overestimate the size of a general factor, and a better but not perfect estimate of total test reliability because it underestimates total reliability. None the less, it is a common statistic to report. In general, the use of alpha should be discouraged and the use of more appropriate estimates ($\omega_h$ and $\omega_t$) should be encouraged.

Correlations between scales are attenuated by a lack of reliability. Correcting correlations for reliability (by dividing by the square roots of the reliabilities of each scale) sometimes help show structure. This is done in the scale intercorrelation matrix with raw correlations below the diagonal and unattenuated correlation above the diagonal.

There are several alternative ways to treat missing values. By default, missing values are replaced with the corresponding median value for that item. Means can be used instead (impute="mean"), or subjects with missing data can just be dropped (missing = FALSE). For data with a great deal of missingness, yet another option is to just find the average of the available responses (impute="none"). This is useful for findings means for scales for the SAPA project (see https://sapa-project.org) where most scales are estimated from random sub samples of the items from the scale. In this case, the alpha reliabilities are seriously overinflated because they are based upon the total number of items in each scale. The "alpha observed" values are based upon the
average number of items answered in each scale using the standard form for alpha a function of inter-item correlation and number of items.

Using the impute="none" option as well as asking for totals (totals="TRUE") will be done, although a warning will be issued because scores will now reflect the number of items responded to much more than the actual pattern of responses.

The number of missing responses for each person for each scale is reported in the missing object. One possibility is to drop scores just for those scales with missing responses. This may be done adding the code:

```r
scores$scores[scores$missing >0] <- NA
```

This is shown in the last example.

Note that the default for scoreItems is to impute missing items with their median, but the default for scoreFast is to not impute but must return the scale scores based upon the mean or total value for the items scored.

scoreItems can be applied to correlation matrices to find just the reliability statistics. This will be done automatically if the items matrix is symmetric.

scoreFast just finds the scores (with or without imputation) and does not report other statistics. It is much faster! scoreVeryFast is even more stripped down, no imputation, just scores based upon the observed data. No statistics.

### Value

- **scores**: Sum or average scores for each subject on the k scales
- **alpha**: Cronbach’s coefficient alpha. A simple (but non-optimal) measure of the internal consistency of a test. See also beta and omega. Set to 1 for scales of length 1.
- **av.r**: The average correlation within a scale, also known as alpha 1, is a useful index of the internal consistency of a domain. Set to 1 for scales with 1 item.
- **G6**: Guttman’s Lambda 6 measure of reliability
- **G6***: A generalization of Guttman’s Lambda 6 measure of reliability using all the items to find the smc.
- **n.items**: Number of items on each scale
- **item.cor**: The correlation of each item with each scale. Because this is not corrected for item overlap, it will overestimate the amount that an item correlates with the other items in a scale.
- **cor**: The intercorrelation of all the scales based upon the interitem correlations (see note for why these differ from the correlations of the observed scales themselves).
- **corrected**: The correlations of all scales (below the diagonal), alpha on the diagonal, and the unattenuated correlations (above the diagonal)
- **item.corrected**: The item by scale correlations for each item, corrected for item overlap by replacing the item variance with the smc for that item
- **response.freq**: The response frequency (based upon number of non-missing responses) for each alternative.
- **missing**: How many items were not answered for each scale
- **num.ob.item**: The average number of items with responses on a scale. Used in calculating the alpha.observed–relevant for SAPA type data structures.
Note

It is important to recognize in the case of massively missing data (e.g., data from a Synthetic Aperture Personality Assessment (https://sapa-project.org) or the International Cognitive Ability Resources (https://icar-project.org)) study where perhaps only 10-50% of the items per scale are given to any one subject) that the number of items per scale, and hence standardized alpha, is not the nominal value and hence alpha of the observed scales will be overestimated. For this case (impute="none"), an additional alpha (alpha.ob) is reported.

More importantly in this case of massively missing data, there is a difference between the correlations of the composite scales based upon the correlations of the items and the correlations of the scored scales based upon the observed data. That is, the cor object will have correlations as if all items had been given, while the correlation of the scores object will reflect the actual correlation of the scores. For SAPA data, it is recommended to use the cor object. Confidence of these correlations may be found using the cor.ci function.

Further note that the inter-scale correlations are based upon the correlations of scales formed from the covariance matrix of the items. This will differ from the correlation of scales based upon the correlation of the items. Thus, although scoreItems will produce reliabilities and intercorrelations from either the raw data or from a correlation matrix, these values will differ slightly. In addition, with a great deal of missing data, the scale intercorrelations will differ from the correlations of the scores produced, for the latter will be attenuated.

An alternative to classical test theory scoring is to use scoreIrt to find score estimates based upon Item Response Theory. This is particularly useful in the case of SAPA data which tend to be massively missing. It is also useful to find scores based upon polytomous items following a factor analysis of the polychoric correlation matrix (see irt.fa). However, remember that this only makes sense if the items are unidimensional. That is to say, if forming item composites from (e.g., bestScales), that are empirically derived, they will necessarily have a clear factor structure and the IRT based scoring does not make sense.

When reverse scoring items from a set where items differ in their possible minima or maxima, it is important to specify the min and max values. Items are reversed by subtracting them from max + min. Thus, if items range from 1 to 6, items are reversed by subtracting them from 7. But, if the data set includes other variables, (say an id field) that far exceeds the item min or max, then the max id will incorrectly be used to reverse key. min and max can either be single values, or vectors for all items. Compare two examples of scoring the bfi data set.

If scales are formed with overlapping items, then the correlations of the scales will be seriously inflated. scoreOverlap will adjust the correlations for this overlap.

Yet another possibility for scoring large data sets is to ignore all the reliability calculations and just find the scores. This may be done using scoreFast or scoreVeryFast. These two functions just find mean scores (scoreVeryFast without imputation) or will do imputation if desired scoreFast. For 200K cases on 1000 variables with 11 scales, scoreVeryFast took 4.7 seconds on a Mac PowerBook with a 2.8GHZ Intel I7 and scoreFast took 23.2 seconds. scoreIrt.1pl for the same problem took xxx with options("mc.cores"=1) (not parallel processing) and 1259 seconds with options("mc.cores"=NULL) (implying 2 cores) and with four cores was very slow (probably too much parallel processing).

Yet one more possibility is to find scores based upon a matrix of weights (e.g. zero order correlations, beta weights, or factor weights.) In this case, scores are simply the product of the weights times the (standardized) items. If using coefficients from a regression analysis (lm), a column of 1's is added to the data and labeled "(Intercept)" and this is used in the calculation. This is done by scoreWtd.

make.keys for a convenient way to create the keys file, score.multiple.choice for multiple choice items,
alpha, correct.cor, cluster.cor, cluster.loadings, omega, guttman for item/scale analysis.
If scales are formed from overlapping sets of items, their correlations will be inflated. This is corrected for when using the scoreOverlap function which, although it will not produce scores, will report scale intercorrelations corrected for item overlap.
In addition, the irt.fa function provides an alternative way of examining the structure of a test and emphasizes item response theory approaches to the information returned by each item and the total test. Associated with these IRT parameters is the scoreIrt function for finding IRT based scores as well as irt.responses to show response curves for the alternatives in a multiple choice test.
scoreIrt will find both IRT based estimates as well as average item response scores. These latter correlate perfectly with those found by scoreItems. If using a keys matrix, the score.irt results are based upon the item difficulties with the assumption that all items are equally discriminating (effectively a Rasch model). These scores are probably most useful in the case of massively missing data because they can take into account the item difficulties.
scoreIrt.1pl finds the item difficulty parameters and then applies a 1 parameter (Rasch like) model. It chooses items based upon a keys.list.

Examples
#see the example including the bfi data set
data(psychTools::bfi)
keys.list <- list(agree=c("-A1","A2","A3","A4","A5"),
                conscientious=c("C1","C2","C3","-C4","-C5"),
                extraversion=c("E1","-E2","E3","E4","E5"),
                neuroticism=c("N1","N2","N3","N4","N5"),
                openness = c("O1","-O2","O3","O4","-O5"))
keys <- make.keys(psychTools::bfi,keys.list) #no longer necessary
scores <- scoreItems(keys,psychTools::bfi,min=1,max=6) #using a keys matrix
scoreOverlap

Find correlations of composite variables (corrected for overlap) from a larger matrix.

Description

Given a n x c cluster definition matrix of -1s, 0s, and 1s (the keys), and a n x n correlation matrix, or an N x n data matrix, find the correlations of the composite clusters. The keys matrix can be entered by hand, copied from the clipboard (read.clipboard), or taken as output from the factor2cluster or make.keys functions. Similar functionality to scoreItems which also gives item by cluster correlations.

Usage

scoreOverlap(keys, r, correct = TRUE, SMC = TRUE, av.r = TRUE, item.smc = NULL, impute = TRUE, select=TRUE)

cluster.cor(keys, r.mat, correct = TRUE,SMC=TRUE,item.smc=NULL,impute=TRUE)

Arguments

keys A list of scale/cluster keys, or a matrix of cluster keys
r.mat A correlation matrix
r Either a correlation matrix or a raw data matrix
correct TRUE shows both raw and corrected for attenuation correlations
Should squared multiple correlations be used as communality estimates for the correlation matrix?

the smcs of the items may be passed into the function for speed, or calculated if SMC=TRUE

if TRUE, impute missing scale correlations based upon the average interitem correlation, otherwise return NA.

Should the average r be used in correcting for overlap? smcs otherwise.

By default, just find statistics for items included in the scoring keys. This allows for finding scores from matrices with bad items if they are not included in the set of scoring keys.

This are two of the functions used in the SAPA (https://sapa-project.org) procedures to form synthetic correlation matrices. Given any correlation matrix of items, it is easy to find the correlation matrix of scales made up of those items. This can also be done from the original data matrix or from the correlation matrix using scoreItems which is probably preferred unless the keys are overlapping.

In the case of overlapping keys, (items being scored on multiple scales), scoreOverlap will adjust for this overlap by replacing the overlapping covariances (which are variances when overlapping) with the corresponding best estimate of an item’s “true” variance using either the average correlation or the smc estimate for that item. This parallels the operation done when finding alpha reliability. This is similar to ideas suggested by Cureton (1966) and Bashaw and Anderson (1966) but uses the smc or the average interitem correlation (default).

A typical use in the SAPA project is to form item composites by clustering or factoring (see fa, ICLUST, principal), extract the clusters from these results (factor2cluster), and then form the composite correlation matrix using cluster.cor. The variables in this reduced matrix may then be used in multiple correlatin procedures using mat.regress.

The original correlation is pre and post multiplied by the (transpose) of the keys matrix.

If some correlations are missing from the original matrix this will lead to missing values (NA) for scale intercorrelations based upon those lower level correlations. If impute=TRUE (the default), a warning is issued and the correlations are imputed based upon the average correlations of the non-missing elements of each scale.

Because the alpha estimate of reliability is based upon the correlations of the items rather than upon the covariances, this estimate of alpha is sometimes called “standardized alpha”. If the raw items are available, it is useful to compare standardized alpha with the raw alpha found using scoreItems. They will differ substantially only if the items differ a great deal in their variances.

scoreOverlap answers an important question when developing scales and related subscales, or when comparing alternative versions of scales. For by removing the effect of item overlap, it gives a better estimate the relationship between the latent variables estimated by the observed sum (mean) scores.

the (raw) correlation matrix of the clusters
standard deviation of the cluster scores
raw correlations below the diagonal, alphas on diagonal, disattenuated above diagonal
The (standardized) alpha reliability of each scale.
G6

Guttman's Lambda 6 reliability estimate is based upon the smcs for each item in a scale. G6 uses the smc based upon the entire item domain.

av. r

The average inter item correlation within a scale

size

How many items are in each cluster?

Note

The second example uses the msq data set of 72 measures of motivational state to examine the overlap between four lower level scales and two higher level scales.

summary(adjusted.scales)
#note that the EA and high and low EA and TA and high and low TA
# scale correlations are confounded
summary(confounded.scales)

scoreWtd

Score items using regression or correlation based weights

Description

Item weights from bestScales or setCor are used to find weighted scale scores. In contrast to the unit weights used in scoreItems, scoreWtd will multiply the data by a set of weights to find scale scores. These weight may come from a regression (e.g., lm or setCor) or may be the zero order correlation weights from bestScales.

Usage

scoreWtd(weights, items, std = TRUE, sums = FALSE, impute = "none")

Arguments

weights This is just a matrix of weights to use for each item for each scale.
items Matrix or dataframe of raw item scores
std if TRUE, then find weighted standard scores else just use raw data
sums By default, find the average item score. If sums = TRUE, then find the sum scores. This is useful for regression with an intercept term
impute impute="median" replaces missing values with the item medians, impute = "mean" replaces values with the mean response. impute="none" the subject’s scores are based upon the average of the keyed, but non missing scores. impute = "none" is probably more appropriate for a large number of missing cases (e.g., SAPA data).

Details

Although meant for finding correlation weighted scores using the weights from bestScales, it also possible to use alternative weight matrices, such as those returned by the coefficients in lm.

Value

A data frame of scores.

bestScales and setCor
Examples

#find the weights from a regression model and then apply them to a new set
#derivation of weights from the first 20 cases
model.lm <- lm(rating ~ complaints + privileges + learning, data=attitude[1:20,])
#or use setCor to find the coefficients
model <- setCor(rating ~ complaints + privileges + learning, data=attitude[1:20,], std=FALSE)

#Apply these to a different set of data (the last 10 cases)
#note that the regression coefficients need to be a matrix
scores.lm <- scoreWtd(as.matrix(model.lm$coefficients), attitude[21:30,], sums=TRUE, std=FALSE)
scores <- scoreWtd(model$coefficients, attitude[21:30,], sums=TRUE, std=FALSE)
describe(scores)

scrub

A utility for basic data cleaning and recoding. Changes values outside of minimum and maximum limits to NA.

Description

A tedious part of data analysis is addressing the problem of miscoded data that need to be converted to NA or some other value. For a given data.frame or matrix, scrub will set all values of columns from=from to=to that are less than a set (vector) of min values or more than a vector of max values to NA. Can also be used to do basic recoding of data for all values=isvalue to newvalue.

The length of the where, isvalue, and newvalues must either match, or be 1.

Usage

scrub(x, where, min, max, isvalue, newvalue)

Arguments

x a data frame or matrix
where The variables to examine. (Can be by name or by column number)
min a vector of minimum values that are acceptable
max a vector of maximum values that are acceptable
isvalue a vector of values to be converted to newvalue (one per variable)
newvalue a vector of values to replace those that match isvalue

Details

Solves a tedious problem that can be done directly but that is sometimes awkward. Will either replace specified values with NA or

Value

The corrected data frame.
Note

Probably could be optimized to avoid one loop

reverse.code, rescale for other simple utilities.

Examples

data(attitude)
x <- scrub(attitude, isvalue=55) # make all occurrences of 55 NA
x1 <- scrub(attitude, where=c(4,5,6), isvalue=c(30,40,50),
    newvalue = c(930,940,950)) # will do this for the 4th, 5th, and 6th variables
x2 <- scrub(attitude, where=c(4,4,4), isvalue=c(30,40,50),
    newvalue = c(930,940,950)) # will just do it for the 4th column
# get rid of a complicated set of cases and replace with missing values
y <- scrub(attitude, where=2:4, min=c(20,30,40), max= c(120,110,100), isvalue= c(32,43,54))
y1 <- scrub(attitude, where=“learning”, isvalue=55, newvalue=999) # change a column by name
y2 <- scrub(attitude, where=“learning”, min=45, newvalue=999) # change a column by name
y3 <- scrub(attitude, where=“learning”, isvalue=c(45,48),
    newvalue=999) # change a column by name look for multiple values in that column
y4 <- scrub(attitude, where=“learning”, isvalue=c(45,48),
    newvalue = c(999,-999)) # change values in one column to one of two different things

SD

Find the Standard deviation for a vector, matrix, or data.frame - do not return error if there are no cases

Description

Find the standard deviation of a vector, matrix, or data.frame. In the latter two cases, return the sd of each column. Unlike the sd function, return NA if there are no observations rather than throw an error.

Usage

SD(x, na.rm = TRUE) # deprecated

Arguments

x a vector, data.frame, or matrix
na.rm na.rm is assumed to be TRUE

Details

Finds the standard deviation of a vector, matrix, or data.frame. Returns NA if no cases. Just an adaptation of the stats:sd function to return the functionality found in R < 2.7.0 or R >= 2.8.0 Because this problem seems to have been fixed, SD will be removed eventually.
**Value**

The standard deviation

**Note**

Until R 2.7.0, sd would return a NA rather than an error if no cases were observed. SD brings back that functionality. Although unusual, this condition will arise when analyzing data with high rates of missing values. This function will probably be removed as 2.7.0 becomes outdated.

**Author(s)**

William Revelle

**See Also**

These functions use SD rather than sd: `describe.by`, `skew`, `kurtosi`

**Examples**

data(attitude)
apply(attitude,2,sd) #all complete
attitude[,1] <- NA
SD(attitude) #missing a column
describe(attitude)
setCor

Arguments

- **y**: Three options: 'formula' form (similar to lm) or either the column numbers of the y set (e.g., c(2,4,6)) or the column names of the y set (e.g., c("Flags","Addition"). See notes and examples for each.
- **x**: either the column numbers of the x set (e.g., c(1,3,5)) or the column names of the x set (e.g. c("Cubes","PaperFormBoard"). x and y may also be set by use of the formula style of lm.
- **data**: A matrix or data.frame of correlations or, if not square, of raw data
- **C**: A variance/covariance matrix, or a correlation matrix
- **m**: The column name or numbers of the set of mediating variables (see mediate).
- **z**: the column names or numbers of the set of covariates.
- **n.obs**: If specified, then confidence intervals, etc. are calculated, not needed if raw data are given.
- **use**: find the correlations using "pairwise" (default) or just use "complete" cases (to match the lm function)
- **std**: Report standardized betas (based upon the correlations) or raw bs (based upon covariances)
- **raw**: Are data from a correlation matrix or data matrix?
- **means**: A vector of means for the data in matReg if giving matrix input
- **main**: The title for setCor.diagram
- **square**: if FALSE, then square matrices are treated as correlation matrices not as data matrices. In the rare case that one has as many cases as variables, then set square=TRUE.
- **sc**: The output of setCor may be used for drawing diagrams
- **digits**: How many digits should be displayed in the setCor.diagram?
- **show**: Show the unweighted matrix correlation between the x and y sets?
- **zero**: zero center the data before finding the interaction terms.
- **alpha**: p value of the confidence intervals for the beta coefficients
- **plot**: By default, setCor makes a plot of the results, set to FALSE to suppress the plot
- **cex**: Text size of boxes displaying the variables in the diagram
- **l.cex**: Text size of numbers in arrows, defaults to cex
- **...**: Additional graphical parameters for setCor.diagram

Details

Although it is more common to calculate multiple regression and canonical correlations from the raw data, it is, of course, possible to do so from a matrix of correlations or covariances. In this case, the input to the function is a square covariance or correlation matrix, as well as the column numbers (or names) of the x (predictor), y (criterion) variables, and if desired z (covariates). The function will find the correlations if given raw data.

Input is either the set of y variables and the set of x variables, this can be written in the standard formula style of lm (see last example). In this case, pairwise or higher interactions (product terms) may also be specified. By default, when finding product terms, the data are zero centered (Cohen, Cohen, West and Aiken, 2003), although this option can be turned off (zero=FALSE) to match the results of lm or the results discussed in Hayes (2013).
Covariates to be removed are specified by a negative sign in the formula input or by using the z variable. Note that when specifying covariates, the regressions are done as if the regressions were done on the partialled variables. This means that the degrees of freedom and the R2 reflect the regressions of the partialled variables. (See the last example.)

The output is a set of multiple correlations, one for each dependent variable in the y set, as well as the set of canonical correlations.

An additional output is the R2 found using Cohen’s set correlation (Cohen, 1982). This is a measure of how much variance and the x and y set share.

Cohen (1982) introduced the set correlation, a multivariate generalization of the multiple correlation to measure the overall relationship between two sets of variables. It is an application of canonical correlation (Hotelling, 1936) and \[ 1 - \prod (1 - \rho^2_i) \] where \( \rho^2_i \) is the squared canonical correlation. Set correlation is the amount of shared variance (R2) between two sets of variables. With the addition of a third, covariate set, set correlation will find multivariate R2, as well as partial and semi partial R2. (The semi and bipartial options are not yet implemented.) Details on set correlation may be found in Cohen (1982), Cohen (1988) and Cohen, Cohen, Aiken and West (2003).

R2 between two sets is just

\[
R^2 = 1 - \frac{|R_{xy}|}{|R_y|\,|R_x|} = 1 - \prod (1 - \rho^2_i)
\]

where R is the complete correlation matrix of the x and y variables and Rx and Ry are the two sets involved.

Unfortunately, the R2 is sensitive to one of the canonical correlations being very high. An alternative, T2, is the proportion of additive variance and is the average of the squared canonicals. (Cohen et al., 2003), see also Cramer and Nicewander (1979). This average, because it includes some very small canonical correlations, will tend to be too small. Cohen et al. admonition is appropriate: "In the final analysis, however, analysts must be guided by their substantive and methodological conceptions of the problem at hand in their choice of a measure of association." (p613).

Yet another measure of the association between two sets is just the simple, unweighted correlation between the two sets. That is,

\[
R_{uw} = \frac{1R_{xy}1'}{(1R_{yy}1')^{\frac{1}{2}}(1R_{xx}1')^{\frac{1}{2}}}
\]

where Rxy is the matrix of correlations between the two sets. This is just the simple (unweighted) sums of the correlations in each matrix. This technique exemplifies the robust beauty of linear models and is particularly appropriate in the case of one dimension in both x and y, and will be a drastic underestimate in the case of items where the betas differ in sign.

When finding the unweighted correlations, as is done in alpha, items are flipped so that they all are positively signed.

A typical use in the SAPA project is to form item composites by clustering or factoring (see fa, ICLUST, principal), extract the clusters from these results (factor2cluster), and then form the composite correlation matrix using cluster.cor. The variables in this reduced matrix may then be used in multiple R procedures using setCor.

Although the overall matrix can have missing correlations, the correlations in the subset of the matrix used for prediction must exist.

If the number of observations is entered, then the conventional confidence intervals, statistical significance, and shrinkage estimates are reported.

If the input is rectangular (not square), correlations or covariances are found from the data.
The print function reports t and p values for the beta weights, the summary function just reports the beta weights.

The Variance Inflation Factor is reported but should be taken with the normal cautions of interpretation discussed by Guide and Ketokivm. That is to say, VIF > 10 is not a magic cuttoff to define colinearity. It is merely 1/(1-smc(R(x)).

matReg is primarily a helper function for mediate but is a general multiple regression function given a covariance matrix and the specified x, y and z variables. Its output includes betas, se, t, p and R2. The call includes m for mediation variables, but these are only used to adjust the degrees of freedom. matReg does not work on data matrices, nor does it take formula input. It is really just a helper function for mediate.

</tbody>
</table>

**Note**

As of April 30, 2011, the order of x and y was swapped in the call to be consistent with the general y ~ x syntax of the lm and aov functions. In addition, the primary name of the function was switched to setCor from mat.regress to reflect the estimation of the set correlation.

In October, 2017 I added the ability to specify the input in formula mode and allow for higher level and multiple interactions.

The denominator degrees of freedom for the set correlation does not match that reported by Cohen et al., 2003 in the example on page 621 but does match the formula on page 615, except for the typo in the estimation of F (see Cohen 1982). The difference seems to be that they are adding in a correction factor of df 2 = df2 + df1.

**Description**

A number of functions in the psych package will generate simulated data with particular structures. These functions include `sim` for a factor simplex, and `sim.simplex` for a data simplex, `sim.circ` for a circular simplex, and `sim.to.data` for generating data given covariances.
for a circumplex structure, `sim.congeneric` for a one factor factor congeneric model, `sim.dichot` to simulate dichotomous items, `sim.hierarchical` to create a hierarchical factor model, `sim.item` a more general item simulation, `sim.minor` to simulate major and minor factors, `sim.parallel` to compare the efficiency of various ways of determining the number of factors, `sim.rasch` to create simulated rasch data, `sim.irt` to create general 1 to 4 parameter IRT data by calling `sim.npl` 1 to 4 parameter logistic IRT or `sim.npn` 1 to 4 parameter normal IRT. `sim.poly` to create polytomous ideas by calling `sim.poly.npn` 1-4 parameter polytomous normal theory items or `sim.poly.npl` 1-4 parameter polytomous logistic items, and `sim.poly.ideal` which creates data following an ideal point or unfolding model by calling `sim.poly.ideal.npn` 1-4 parameter polytomous normal theory ideal point model or `sim.poly.ideal.npl` 1-4 parameter polytomous logistic ideal point model.

`sim.structural` a general simulation of structural models, and `sim.anova` for ANOVA and lm simulations, and `sim.VSS`. Some of these functions are separately documented and are listed here for ease of the help function. See each function for more detailed help.

**Usage**

```r
sim(fx=NULL, Phi=NULL, fy=NULL, alpha=.8, lambda = 0, n=0, mu=NULL, raw=TRUE)
sim.simplex(nvar =12, alpha=.8, lambda=0, beta=1, mu=NULL, n=0)
sim.general(nvar=9, nfact =3, g=.3, r=.3, n=0)
sim.minor(nvar=12, nfact=3, n=0, g=NULL, fbig=NULL, fsmall = c(-.2, .2), bipolar=TRUE)
sim.omega(nvar=12, nfact=3, n=500, g=NULL, sem=FALSE, fbig=NULL, fsmall = c(-.2, .2), bipolar=TRUE, om.fact=3, flip=TRUE, option="equal", ntrials=10)
sim.parallel(ntrials=10, nvar = c(12,24,36,48), nfact = c(1,2,3,4,6), n = c(200,400))
sim.rasch(nvar = 5, n = 500, low=-3, high=3, d=NULL, a=1, mu=0, sd=1)
sim.irt(nvar = 5, n = 500, low=-3, high=3, d=NULL, c=0, z=1, d=0, mu=0, sd=1, mod="logistic", theta=NULL)
sim.npl(nvar = 5, n = 500, low=-3, high=3, a=NULL, c=0, z=1, d=0, mu=0, sd=1, theta=NULL)
sim.npn(nvar = 5, n = 500, low=-3, high=3, a=NULL, c=0, z=1, d=0, mu=0, sd=1, theta=NULL)
sim.poly(nvar = 5, n = 500, low=-2, high=2, a=NULL, c=0, z=1, d=0, mu=0, sd=1, cat=5, mod="logistic", theta=NULL)
sim.poly.npn(nvar = 5, n = 500, low=-2, high=2, a=NULL, c=0, z=1, d=0, mu=0, sd=1, cat=5, theta=NULL)
sim.poly.npl(nvar = 5, n = 500, low=-2, high=2, a=NULL, c=0, z=1, d=0, mu=0, sd=1, cat=5, theta=NULL)
sim.poly.ideal(nvar = 5, n = 500, low=-2, high=2, a=NULL, c=0, z=1, d=0, mu=0, sd=1, cat=5, mod="logistic")
sim.poly.ideal.npn(nvar = 5, n = 500, low=-2, high=2, a=NULL, c=0, z=1, d=0, mu=0, sd=1, cat=5)
sim.poly.ideal.npl(nvar = 5, n = 500, low=-2, high=2, a=NULL, c=0, z=1, d=0, mu=0, sd=1, cat=5)
sim.poly.mat(R, m, n)
```

**Arguments**

- `fx` The measurement model for x. If `NULL`, a 4 factor model is generated
- `Phi` The structure matrix of the latent variables
- `fy` The measurement model for y
- `mu` The means structure for the fx factors
- `n` Number of cases to simulate. If `n=0` or `NULL`, the population matrix is returned.
if raw=TRUE, raw data are returned as well.

Number of variables for a simplex structure

Number of large factors to simulate in sim.minor, number of group factors in sim.general, sim.omega

General factor correlations in sim.general and general factor loadings in sim.omega and sim.minor

Should the sim.omega function do both an EFA omega as well as a CFA omega using the sem package?

group factor correlations in sim.general

the base correlation for an autoregressive simplex

the trait component of a State Trait Autoregressive Simplex

Test reliability of a STARS simplex

Factor loadings for the main factors. Default is a simple structure with loadings sampled from (.8,.6) for nvar/nfact variables and 0 for the remaining. If fbig is specified, then each factor has loadings sampled from it.

if TRUE, then positive and negative loadings are generated from fbig

Number of factors to extract in omega

In omega, should item signs be flipped if negative

In omega, for the case of two factors, how to weight them?

nvar/2 small factors are generated with loadings sampled from (-.2,0,.2)

Number of replications per level

lower difficulty for sim.rasch or sim.irt

higher difficulty for sim.rasch or sim.irt

if not specified as a vector, the descrimination parameter $a = \alpha$ will be set to 1.0 for all items

if not specified as a vector, item difficulties ($d = \delta$) will range from low to high

the gamma parameter: if not specified as a vector, the guessing asymptote is set to 0

the zeta parameter: if not specified as a vector, set to 1

the standard deviation for the underlying latent variable in the irt simulations

which IRT model to use, mod="logistic" simulates a logistic function, otherwise, a normal function

Number of categories to simulate in sim.poly. If cat=2, then this is the same as simulating t/f items and sim.poly is functionally equivalent to sim.irt

The underlying latent trait value for each simulated subject

A correlation matrix to be simulated using the sim.poly.mat function

The matrix of marginals for all the items

Simulation of data structures is a very useful tool in psychometric research and teaching. By knowing "truth" it is possible to see how well various algorithms can capture it. For a much longer discussion of the use of simulation in psychometrics, see the accompany vignettes.
The simulations documented here are a miscellaneous set of functions that will be documented in other help files eventually.

The default values for `sim.structure` is to generate a 4 factor, 12 variable data set with a simplex structure between the factors. This, and the simplex of items (`sim.simplex`) can also be converted in a STARS model with an autoregressive component (alpha) and a stable trait component (lambda).

Two data structures that are particular challenges to exploratory factor analysis are the simplex structure and the presence of minor factors. Simplex structures `sim.simplex` will typically occur in developmental or learning contexts and have a correlation structure of r between adjacent variables and r^n for variables n apart. Although just one latent variable (r) needs to be estimated, the structure will have nvar-1 factors.

An alternative version of the simplex is the State-Trait-Auto Regressive Structure (STARS) which has both a simplex state structure, with autoregressive path alpha and a trait structure with path lambda. This simulated in `sim.simplex` by specifying a non-zero lambda value.

Many simulations of factor structures assume that except for the major factors, all residuals are normally distributed around 0. An alternative, and perhaps more realistic situation, is that there are a few major (big) factors and many minor (small) factors. The challenge is thus to identify the major factors. `sim.minor` generates such structures. The structures generated can be thought of as having a major factor structure with some small correlated residuals. To make these simulations complete, the possibility of a general factor is considered. For simplicity, `sim.minor` allows one to specify a set of loadings to be sampled from for g, fmajor and fminor. Alternatively, it is possible to specify the complete factor matrix.

Another structure worth considering is direct modeling of a general factor with several group factors. This is done using `sim.general`.

Although coefficient $\omega$ is a very useful indicator of the general factor saturation of a unifactorial test (one with perhaps several sub factors), it has problems with the case of multiple, independent factors. In this situation, one of the factors is labelled as “general” and the omega estimate is too large. This situation may be explored using the `sim.omega` function with general left as NULL. If there is a general factor, then results from `sim.omega` suggests that omega estimated either from EFA or from SEM does a pretty good job of identifying it but that the EFA approach using Schmid-Leiman transformation is somewhat more robust than the SEM approach.

The four irt simulations, `sim.rasch`, `sim.irt`, `sim.npl` and `sim.npn`, simulate dichotomous items following the Item Response model. `sim.irt` just calls either `sim.npl` (for logistic models) or `sim.npn` (for normal models) depending upon the specification of the model.

The logistic model is

$$ P(i,j) = \gamma + \frac{\zeta - \gamma}{1 + e^{\alpha(\delta - \theta)}} $$

where $\gamma$ is the lower asymptote or guessing parameter, $\zeta$ is the upper asymptote (normally 1), $\alpha$ is item discrimination and $\delta$ is item difficulty. For the 1 Parameter Logistic (Rasch) model, gamma=0, zeta=1, alpha=1 and item difficulty is the only free parameter to specify.

For the 2PL and 2PN models, $a = \alpha$ and $d = \delta$ are specified.

For the 3PL or 3PN models, items also differ in their guessing parameter $c = \gamma$.

For the 4PL and 4PN models, the upper asymptote, $z = \zeta$ is also specified.

(Graphics of these may be seen in the demonstrations for the `logistic` function.)

The normal model (`irt.npn`) calculates the probability using `pnorm` instead of the logistic function used in `irt.npl`, but the meaning of the parameters are otherwise the same. With the $a = \alpha$ parameter = 1.702 in the logistic model the two models are practically identical.

In parallel to the dichotomous IRT simulations are the poly versions which simulate polytomous item models. They have the additional parameter of how many categories to simulate. In addition, the `sim.poly.ideal` functions will simulate an ideal point or unfolding model in which the
response probability varies by the distance from each subject’s ideal point. Some have claimed that this is a more appropriate model of the responses to personality questionnaires. It will lead to simplex like structures which may be fit by a two factor model. The middle items form one factor, the extreme a bipolar factor.

By default, the theta parameter is created in each function as normally distributed with mean mu=0 and sd=1. In the case where you want to specify the theta to be equivalent from another simulation or fixed for a particular experimental condition, either take the theta object from the output of a previous simulation, or create it using whatever properties are desired.

The previous functions all assume one latent trait. Alternatively, we can simulate dichotomous or polytomous items with a particular structure using the sim.poly.mat function. This takes as input the population correlation matrix, the population marginals, and the sample size. It returns categorical items with the specified structure.

Other simulation functions in psych are:

- **sim.structure** A function to combine a measurement and structural model into one data matrix. Useful for understanding structural equation models. Combined with structure.diagram to see the proposed structure.

- **sim.congeneric** A function to create congeneric items/tests for demonstrating classical test theory. This is just a special case of sim.structure.

- **sim.hierarchical** A function to create data with a hierarchical (bifactor) structure.

- **sim.item** A function to create items that either have a simple structure or a circumplex structure.

- **sim.circ** Create data with a circumplex structure.

- **sim.dichot** Create dichotomous item data with a simple or circumplex structure.

- **sim.minor** Create a factor structure for nvar variables defined by nfact major factors and nvar/2 “minor” factors for n observations.

Although the standard factor model assumes that K major factors (K « nvar) will account for the correlations among the variables

\[
R = FF' + U^2
\]

where R is of rank P and F is a P x K matrix of factor coefficients and U is a diagonal matrix of uniquenesses. However, in many cases, particularly when working with items, there are many small factors (sometimes referred to as correlated residuals) that need to be considered as well. This leads to a data structure such that

\[
R = FF' + MM' + U^2
\]

where R is a P x P matrix of correlations, F is a P x K factor loading matrix, M is a P x P/2 matrix of minor factor loadings, and U is a diagonal matrix (P x P) of uniquenesses.

Such a correlation matrix will have a poor \( \chi^2 \) value in terms of goodness of fit if just the K factors are extracted, even though for all intents and purposes, it is well fit. sim.minor will generate such data sets with big factors with loadings of .6 to .8 and small factors with loadings of -.2 to .2. These may both be adjusted.

- **sim.parallel** Create a number of simulated data sets using sim.minor to show how parallel analysis works. The general observation is that with the presence of minor factors, parallel analysis is probably best done with component eigen values rather than factor eigen values, even when using the factor model.

- **sim.anova** Simulate a 3 way balanced ANOVA or linear model, with or without repeated measures. Useful for teaching research methods and generating teaching examples.
To understand some of the basic concepts of multilevel modeling, it is useful to create multilevel structures. The correlations of aggregated data is sometimes called an ‘ecological correlation’. That group level and individual level correlations are independent makes such inferences problematic. This simulation allows for demonstrations that correlations within groups do not imply, nor are implied by, correlations between group means.

dichot.sim <- sim.irt() #simulate 5 dichotomous items
poly.sim <- sim.poly(theta=dichot.sim$theta) #simulate 5 polytomous items that correlate
#with the dichotomous items
```
sim.anova

Simulate a 3 way balanced ANOVA or linear model, with or without repeated measures.

Description

For teaching basic statistics, it is useful to be able to generate examples suitable for analysis of variance or simple linear models. sim.anova will generate the design matrix of three independent variables (IV1, IV2, IV3) with an arbitrary number of levels and effect sizes for each main effect and interaction. IVs can be either continuous or categorical and can have linear or quadratic effects. Either a single dependent variable or multiple (within subject) dependent variables are generated according to the specified model. The repeated measures are assumed to be tau equivalent with a specified reliability.

Usage

sim.anova(es1 = 0, es2 = 0, es3 = 0, es12 = 0, es13 = 0, es23 = 0, es123 = 0, es11=0,es22=0, es33=0,n = 2,n1 = 2, n2 = 2, n3 = 2, within=NULL,r=.8,factors=TRUE,center = TRUE,std=TRUE)

Arguments

es1  Effect size of IV1
es2  Effect size of IV2
es3  Effect size of IV3
es12  Effect size of the IV1 x IV2 interaction
es13  Effect size of the IV1 x IV3 interaction
es23  Effect size of the IV2 x IV3 interaction
es123  Effect size of the IV1 x IV2 * IV3 interaction
es11  Effect size of the quadratic term of IV1
es22  Effect size of the quadratic term of IV2
es33  Effect size of the quadratic term of IV3
n  Sample size per cell (if all variables are categorical) or (if at least one variable is continuous), the total sample size
n1  Number of levels of IV1 (0) if continuous
n2  Number of levels of IV2
n3  Number of levels of IV3
within  if not NULL, then within should be a vector of the means of any repeated measures.
r  the correlation between the repeated measures (if they exist). This can be thought of as the reliability of the measures.
factors  report the IVs as factors rather than numeric
center  center=TRUE provides orthogonal contrasts, center=FALSE adds the minimum value + 1 to all contrasts
std  Standardize the effect sizes by standardizing the IVs
Details

A simple simulation for teaching about ANOVA, regression and reliability. A variety of demonstrations of the relation between anova and lm can be shown.

The default is to produce categorical IVs (factors). For more than two levels of an IV, this will show the difference between the linear model and anova in terms of the comparisons made.

The within vector can be used to add congenerically equivalent dependent variables. These will have intercorrelations (reliabilities) of r and means as specified as values of within.

To demonstrate the effect of centered versus non-centering, make factors = center=FALSE. The default is to center the IVs. By not centering them, the lower order effects will be incorrect given the higher order interaction terms.

Value

y.df is a data.frame of the 3 IV values as well as the DV values.

IV1 ... IV3 Independent variables 1 ... 3
DV If there is a single dependent variable
DV.1 ... DV.n If within is specified, then the n within subject dependent variables

Examples

```r
set.seed(42)
data.df <- sim.anova(es1=1,es2=.5,es13=1) # one main effect and one interaction
describe(data.df)
pairs.panels(data.df) #show how the design variables are orthogonal

# summary(lm(DV~IV1*IV2*IV3,data=data.df))
summary(aov(DV~IV1*IV2*IV3,data=data.df))
set.seed(42)
#demonstrate the effect of not centering the data on the regression
data.df <- sim.anova(es1=1,es2=.5,es13=1,center=FALSE) #
describe(data.df)
# #this one is incorrect, because the IVs are not centered
summary(lm(DV~IV1*IV2*IV3,data=data.df))
summary(aov(DV~IV1*IV2*IV3,data=data.df)) #compare with the lm model

#now examine multiple levels and quadratic terms
set.seed(42)
data.df <- sim.anova(es1=1,es13=1,n2=3,n3=4,es22=1)
summary(lm(DV~IV1*IV2*IV3,data=data.df))
summary(aov(DV~IV1*IV2*IV3,data=data.df))
pairs.panels(data.df)
#
data.df <- sim.anova(es1=1,es2=-.5,within=c(-1,0,1),n=10)
pairs.panels(data.df)
```
**sim.congeneric**  
*Simulate a congeneric data set*

**Description**

Classical Test Theory (CTT) considers four or more tests to be congenerically equivalent if all tests may be expressed in terms of one factor and a residual error. Parallel tests are the special case where (usually two) tests have equal factor loadings. Tau equivalent tests have equal factor loadings but may have unequal errors. Congeneric tests may differ in both factor loading and error variances.

**Usage**

```r
sim.congeneric(loads = c(0.8, 0.7, 0.6, 0.5), N = NULL, err=NULL, short = TRUE, categorical=FALSE, low=-3, high=3, cuts=NULL)
```

**Arguments**

- `N` How many subjects to simulate. If NULL, return the population model
- `loads` A vector of factor loadings for the tests
- `err` A vector of error variances – if NULL then error = 1 - loading 2
- `short` short=TRUE: Just give the test correlations, short=FALSE, report observed test scores as well as the implied pattern matrix
- `categorical` continuous or categorical (discrete) variables.
- `low` values less than low are forced to low
- `high` values greater than high are forced to high
- `cuts` If specified, and categorical = TRUE, will cut the resulting continuous output at the value of cuts

**Details**

When constructing examples for reliability analysis, it is convenient to simulate congeneric data structures. These are the most simple of item structures, having just one factor. Mainly used for a discussion of reliability theory as well as factor score estimates.

The implied covariance matrix is just pattern %*% t(pattern).

**Value**

- `model` The implied population correlation matrix if N=NULL or short=FALSE, otherwise the sample correlation matrix
- `pattern` The pattern matrix implied by the loadings and error variances
- `r` The sample correlation matrix for long output
- `observed` a matrix of test scores for n tests
- `latent` The latent trait and error scores

**Author(s)**

William Revelle
**References**

**See Also**

`item.sim` for other simulations, `fa` for an example of factor scores, `irt.fa` and `polychoric` for the treatment of item data with discrete values.

**Examples**

```r
test <- sim.congeneric(c(.9,.8,.7,.6))  # just the population matrix
test <- sim.congeneric(c(.9,.8,.7,.6),N=100)  # a sample correlation matrix
test <- sim.congeneric(short=FALSE, N=100)
round(cor(test$observed),2)  # show a congeneric correlation matrix
f1=fa(test$observed,scores=TRUE)
round(cor(f1$scores,test$latent),2)
  # factor score estimates are correlated with but not equal to the factor scores
set.seed(42)
# 500 responses to 4 discrete items
items <- sim.congeneric(N=500,short=FALSE,low=-2,high=2,categorical=TRUE)
d4 <- irt.fa(items$observed)  # item response analysis of congeneric measures
```

**sim.hierarchical**

Create a population or sample correlation matrix, perhaps with hierarchical structure.

**Description**

Create a population orthogonal or hierarchical correlation matrix from a set of factor loadings and factor intercorrelations. Samples of size \( n \) may be then be drawn from this population. Return either the sample data, sample correlations, or population correlations. This is used to create sample data sets for instruction and demonstration.

**Usage**

```r
sim.hierarchical(gload=NULL, fload=NULL, n = 0, raw = FALSE, mu = NULL)
sim.bonds(nvar=9,loads=c(0,0,.5,.6),validity=.8)
make.hierarchical(gload=NULL, fload=NULL, n = 0, raw = FALSE)  # deprecated
```

**Arguments**

- `gload` Loadings of group factors on a general factor
- `fload` Loadings of items on the group factors
- `n` Number of subjects to generate: \( N = 0 \) => population values
- `raw` \( \text{raw=TRUE} \), report the raw data, \( \text{raw=FALSE} \), report the sample correlation matrix.
muhierarchical

**mu**

Means for the individual variables

**nvar**

Number of variables to simulate

**loads**

A vector of loadings that will be sampled (rowwise) to define the factors

**validity**

The factor loadings of ‘pure’ measures of the factor.

**Details**

Many personality and cognitive tests have a hierarchical factor structure. For demonstration purposes, it is useful to be able to create such matrices, either with population values, or sample values.

Given a matrix of item factor loadings (fload) and of loadings of these factors on a general factor (gload), we create a population correlation matrix by using the general factor law ($R = F’ \theta F$ where $\theta = g’g$).

To create sample values, we use code adapted from the `mvrnorm` function in MASS.

The default is to return population correlation matrices. Sample correlation matrices are generated if n > 0. Raw data are returned if raw = TRUE.

The default values for gload and fload create a data matrix discussed by Jensen and Weng, 1994. Although written to create hierarchical structures, if the gload matrix is all 0, then a non-hierarchical structure will be generated.

Yet another model is that of Godfrey H. Thomson (1916) who suggested that independent bonds could produce the same factor structure as a $g$ factor model. This is simulated in `sim.bonds`.

Compare the omega solutions for a `sim.hierarchical` with a `sim.bonds` model. Both produce reasonable values of omega, although the one was generated without a general factor.

**Value**

A matrix of correlations or a data matrix

**Author(s)**

William Revelle

**Examples**

```r
gload <- gload<-matrix(c(.9,.8,.7),nrow=3)  # a higher order factor matrix
fload <-matrix(c(   # a lower order (oblique) factor matrix
  .8,0,0,
  .7,0,0,
  .6,0,0,
```
sim.item

Generate simulated data structures for circumplex, spherical, or simple structure

Description

Rotations of factor analysis and principal components analysis solutions typically try to represent correlation matrices as simple structured. An alternative structure, appealing to some, is a circumplex structure where the variables are uniformly spaced on the perimeter of a circle in a two dimensional space. Generating simple structure and circumplex data is straightforward, and is useful for exploring alternative solutions to affect and personality structure. A generalization to 3 dimensional (spherical) data is straightforward.

Usage

sim.item(nvar = 72, nsub = 500, circum = FALSE, xloading = 0.6, yloading = 0.6, gloading = 0, xbias = 0, ybias = 0, categorical = FALSE, low = -3, high = 3, truncate = FALSE, cutpoint = 0)
sim.circ(nvar = 72, nsub = 500, circum = TRUE, xloading = 0.6, yloading = 0.6, gloading = 0, xbias = 0, ybias = 0, categorical = FALSE, low = -3, high = 3, truncate = FALSE, cutpoint = 0)
sim.dichot(nvar = 72, nsub = 500, circum = FALSE, xloading = 0.6, yloading = 0.6, gloading = 0, xbias = 0, ybias = 0, low = 0, high = 0)
item.dichot(nvar = 72, nsub = 500, circum = FALSE, xloading = 0.6, yloading = 0.6, gloading = 0, xbias = 0, ybias = 0, low = 0, high = 0)
sim.spherical(simple=FALSE, nx=7,ny=12 ,nsub = 500, xloading = .55, yloading = .55,
zloading=.55, gloading=0, xbias=0, ybias = 0, zbias=0,categorical=FALSE,
low=-3,high=3,truncate=FALSE,cutpoint=0)

con2cat(old,cuts=c(0,1,2,3),where)

**Arguments**

- **nvar**: Number of variables to simulate
- **nsub**: Number of subjects to simulate
- **circum**: circum=TRUE is circumplex structure, FALSE is simple structure
- **simple**: simple structure or spherical structure in sim.spherical
- **xloading**: the average loading on the first dimension
- **yloading**: Average loading on the second dimension
- **zloading**: the average loading on the third dimension in sim.spherical
- **gloading**: Average loading on a general factor (default=0)
- **xbias**: To introduce skew, how far off center is the first dimension
- **ybias**: To introduce skew on the second dimension
- **zbias**: To introduce skew on the third dimension – if using sim.spherical
- **categorical**: continuous or categorical variables.
- **low**: values less than low are forced to low (or 0 in item.dichot)
- **high**: values greater than high are forced to high (or 1 in item.dichot)
- **truncate**: Change all values less than cutpoint to cutpoint.
- **cutpoint**: What is the cutpoint
- **nx**: number of variables for the first factor in sim.spherical
- **ny**: number of variables for the second and third factors in sim.spherical
- **old**: a matrix or data frame
- **cuts**: Values of old to be used as cut points when converting continuous values to categorical values
- **where**: Which columns of old should be converted to categorical variables. If missing, then all columns are converted.

**Details**

This simulation was originally developed to compare the effect of skew on the measurement of affect (see Rafaeli and Revelle, 2005). It has been extended to allow for a general simulation of affect or personality items with either a simple structure or a circumplex structure. Items can be continuous normally distributed, or broken down into n categories (e.g., -2, -1, 0, 1, 2). Items can be distorted by limiting them to these ranges, even though the items have a mean of (e.g., 1).

The addition of item.dichot allows for testing structures with dichotomous items of different difficulty (endorsement) levels. Two factor data with either simple structure or circumplex structure are generated for two sets of items, one giving a score of 1 for all items greater than the low (easy) value, one giving a 1 for all items greater than the high (hard) value. The default values for low and high are 0. That is, all items are assumed to have a 50 percent endorsement rate. To examine the effect of item difficulty, low could be -1, high 1. This will lead to item endorsements of .84 for the easy and .16 for the hard. Within each set of difficulties, the first 1/4 are assigned to the first factor, the second to the second factor, the third to the first factor (but with negative loadings) and the fourth to the second factor (but with negative loadings).
It is useful to compare the results of `sim.item` with `sim.hierarchical`. `sim.item` will produce a general factor that runs through all the items as well as two orthogonal factors. This produces a data set that is hard to represent with standard rotation techniques. Extracting 3 factors without rotation and then rotating the 2nd and 3rd factors reproduces the correct solution. But simple oblique rotation of 3 factors, or an \omega analysis do not capture the underlying structure. See the last example.

Yet another structure that might be appealing is fully complex data in three dimensions. That is, rather than having items representing the circumference of a circle, items can be structured to represent equally spaced three dimensional points on a sphere. `sim.spherical` produces such data.

### Value

A data matrix of (nsub) subjects by (nvar) variables.

### Examples

```r
round(cor(circ.sim(nvar=8,nsub=200)),2)
plot(fa(circ.sim(16,500),2)$loadings,main="Circumplex Structure") #circumplex structure
# plot(fa(item.sim(16,500),2)$loadings,main="Simple Structure") #simple structure
# cluster.plot(fa(item.dichot(16,low=0,high=1),2))

set.seed(42)
data <- mnormt::rmnorm(1000, c(0, 0), matrix(c(1, .5, .5, 1), 2, 2)) #continuous data
new <- con2cat(data,c(-1.5,-.5,.5,1.5)) #discreet data
polychoric(new)
# not run
#x12 <- sim.item(12,gloading=.6)
#f3 <- fa(x12,3,rotate="none")
#f3 #observe the general factor
#oblimin(f3$loadings[,2:3]) #show the 2nd and 3 factors.
#f3 <- fa(x12,3) #now do it with oblimin rotation
#f3 # not what one naively expect.
```
**sim.multilevel**

*Simulate multilevel data with specified within group and between group correlations*

**Description**

Multilevel data occur when observations are nested within groups. This can produce correlational structures that are sometimes difficult to understand. These two simulations allow for demonstrations that correlations within groups do not imply, nor are implied by, correlations between group means. The correlations of aggregated data is sometimes called an 'ecological correlation'. That group level and individual level correlations are independent makes such inferences problematic. Within individual data are simulated in sim.multi with a variety of possible within person structures.

**Usage**

```r
sim.multi(n.obs=4, nvar=2, nfact=2, ntrials=96, days=16, mu=0, sigma=1, fact=NULL, loading=.9, phi=0, phi.i=NULL, beta.i=0, mu.i=0, sigma.i = 1, sin.i=0, cos.i=0, AR1=0, f.i=NULL, plot=TRUE)
sim.multilevel(nvar = 9, ngroups = 4, ncases = 16, rwg, rbg, eta)
```

**Arguments**

- `n.obs`: How many subjects should be simulated. Four allows for nice graphics, use more to examine structural properties.
- `nvar`: How many variables are to be simulated?
- `nfact`: How many factors are simulated, defaults to 2
- `ntrials`: How many observations per subject (across time)
- `days`: How many days do these observations reflect? This is relevant if we are adding sine and cosines to the model to model diurnal rhythms.
- `mu`: The grand mean for each variable across subjects
- `sigma`: The between person standard deviation
- `fact`: if NULL, a two factor model is created with loadings of loading or zero in a simple structure form
- `loading`: If fact is NULL, then we create a factor model with loading or zeros
- `phi`: The between person factor intercorrelation
- `phi.i`: The within person factor intercorrelations
- `beta.i`: Within subject rate of change over trials
- `mu.i`: The within subject mean for each subject
- `sigma.i`: the within subject standard deviation
- `sin.i`: To what extent should we diurnally vary by subject?
- `cos.i`: This will specify the within subject diurnal phase (lag)
- `AR1`: Auto regressive value implies error at time t +1 is partly a function of error at time t.
f.i  Factor loadings for each subject
plot  If TRUE, create a lattice plot for each subject
ngroups  The number of groups to simulate
ncases  The number of simulated cases
rwg  The within group correlational structure
rbg  The between group correlational structure
eta  The correlation of the data with the within data

details

The basic concepts of the independence of within group and between group correlations is discussed very clearly by Pedhazur (1997) as well as by Bliese (2009). sim.multilevel generates within subject data to model the traditional two level structure of multilevel data. This is meant to show how within subject data measured over ntrials can vary independently within and between subjects. Furthermore, several variables can correlate within subjects show a person by person factor structure.

Factor scores for n.obs subjects are created for nfact factors with loadings on nvar variables. A simple structure model is assumed, so that the loadings on nvar/fact are set to loading for each factor, the others are set to 0. Factors are allowed to correlate phi between subjects and phi.i for each subject. (Which can be different for each subject). Scores can change over time with a slope of beta.i and can vary diurnally as a function of sine and cosine of time (24 hours/day converted to radians). Error is added to every trial and can be related across trials with a lag of 1. Thus, if we set AR1=1, then the errors at time t = error + error at t -1. This will lead to auto correlations of about .5. (See autoR).

sim.multilevel merely simulates pooled correlations (mixtures of between group and within group correlations) to allow for a better understanding of the problems inherent in multi-level modeling.

Data (wg) are created with a particular within group structure (rwg). Independent data (bg) are also created with a between group structure (rbg). Note that although there are ncases rows to this data matrix, there are only ngroups independent cases. That is, every ngroups case is a repeat. The resulting data frame (xy) is a weighted sum of the wg and bg. This is the inverse procedure for estimating estimating rwg and rbg from an observed rxy which is done by the statsBy function.

\[ r_{xy} = \eta_{within} \times \eta_{within} \times r_{xy,within} + \eta_{between} \times \eta_{between} \times r_{xy,between} \]

value

x.df  A data frame for further analysis using statsBy including nvar variable values for each of n.obs subjects (id) for ntrials.
wg  A matrix (ncases * nvar) of simulated within group scores
bg  A matrix (ncases * nvar) of simulated between group scores
xy  A matrix ncases * (nvar +1) of pooled data

lowerCor(XY$bg) #based upon 9 df

sim.structure

Create correlation matrices or data matrices with a particular measurement and structural model

Description

Structural Equation Models decompose correlation or correlation matrices into a measurement (factor) model and a structural (regression) model. sim.structure creates data sets with known measurement and structural properties. Population or sample correlation matrices with known properties are generated. Optionally raw data are produced.

It is also possible to specify a measurement model for a set of x variables separately from a set of y variables. They are then combined into one model with the correlation structure between the two sets.

Finally, the general case is given a population correlation matrix, generate data that will reproduce (with sampling variability) that correlation matrix. sim.correlation.
Usage

```r
sim.structure(fx=NULL, Phi=NULL, fy=NULL, f=NULL, n=0, uniq=NULL, raw=TRUE, 
items = FALSE, low=-2,high=2,d=NULL,cat=5, mu=0)
sim.structural(fx=NULL, Phi=NULL, fy=NULL, f=NULL, n=0, uniq=NULL, raw=TRUE, 
items = FALSE, low=-2,high=2,d=NULL,cat=5, mu=0) #deprecated
sim.correlation(R,n=1000,data=FALSE)
```

Arguments

- `fx`  
  The measurement model for x
- `Phi`  
  The structure matrix of the latent variables
- `fy`  
  The measurement model for y
- `f`  
  The measurement model
- `n`  
  Number of cases to simulate. If n=0, the population matrix is returned.
- `uniq`  
  The uniquenesses if creating a covariance matrix
- `raw`  
  if raw=TRUE, raw data are returned as well for n > 0.
- `items`  
  TRUE if simulating items, FALSE if simulating scales
- `low`  
  Restrict the item difficulties to range from low to high
- `high`  
  Restrict the item difficulties to range from low to high
- `d`  
  A vector of item difficulties, if NULL will range uniformly from low to high
- `cat`  
  Number of categories when creating binary (2) or polytomous items
- `mu`  
  A vector of means, defaults to 0
- `R`  
  The correlation matrix to reproduce
- `data`  
  if TRUE, return the raw data, otherwise return the sample correlation matrix.

Details

Given the measurement model, fx and the structure model Phi, the model is f %*% Phi %*% t(f). Reliability is f %*% t(f). f %*% f ′ and the reliability for each test is the items communality or just the diag of the model.

If creating a correlation matrix, (uniq=NULL) then the diagonal is set to 1, otherwise the diagonal is diag(model) + uniq and the resulting structure is a covariance matrix.

A special case of a structural model are one factor models such as parallel tests, tau equivalent tests, and congeneric tests. These may be created by letting the structure matrix = 1 and then defining a vector of factor loadings. Alternatively, `sim.congeneric` will do the same.

`sim.correlation` will create data sampled from a specified correlation matrix for a particular sample size. If desired, it will just return the sample correlation matrix. With data=TRUE, it will return the sample data as well.

Value

- `model`  
  The implied population correlation or covariance matrix
- `reliability`  
  The population reliability values
- `r`  
  The sample correlation or covariance matrix
- `observed`  
  If raw=TRUE, a sample data matrix

make.hierarchical for another structural model and make.congeneric for the one factor case. structure.list and structure.list for making symbolic structures.

Examples

```r
#First, create a sem like model with a factor model of x and ys with correlation Phi
fx <- matrix(c(.9,.8,.6,rep(0,4),.6,.8,-.7),ncol=2)
fy <- matrix(c(1,.5,.4,ncol=1)
rownames(fx) <- c("V","Q","A","nach","Anx")
rownames(fy) <- c("gpa","Pre","MA")
Phi <- matrix(c(1,0,.7,.0,1,.7,.7,.7,1),ncol=3)
#now create this structure
gre.gpa <- sim.structural(fx,Phi,fy)
print(gre.gpa,2)
#correct for attenuation to see structure
#the raw correlations are below the diagonal, the adjusted above
round(correct.cor(gre.gpa$model,gre.gpa$reliability),2)

#These are the population values,
GRE.GPA <- sim.structural(fx,Phi,fy,n=250,raw=FALSE)
lowerMat(GRE.GPA$r)

#or we can show data sampled from such a population
GRE.GPA <- sim.structural(fx,Phi,fy,n=250,raw=TRUE)
lowerCor(GRE.GPA$observed)

congeneric <- sim.structure(f=c(.9,.8,.7,.6)) # a congeneric model
congeneric

#now take this correlation matrix as a population value and create samples from it
example.congeneric <- sim.correlation(congeneric$model,n=200) #create a sample matrix
lowerMat(example.congeneric) #show the correlation matrix

#or create another sample and show the data
example.congeneric.data <- sim.correlation(congeneric$model,n=200,data=TRUE)
describe(example.congeneric.data)
lowerCor(example.congeneric.data)
```
**Description**

Simulation is one of most useful techniques in statistics and psychometrics. Here we simulate a correlation matrix with a simple structure composed of a specified number of factors. Each item is assumed to have complexity one. See `circ.sim` and `item.sim` for alternative simulations.

**Usage**

```r
sim.VSS(ncases=1000, nvariables=16, nfactors=4, meanloading=.5,dichot=FALSE,cut=0)
```

**Arguments**

- `ncases`: number of simulated subjects
- `nvariables`: Number of variables
- `nfactors`: Number of factors to generate
- `meanloading`: with a mean loading
- `dichot`: dichot=FALSE give continuous variables, dichot=TRUE gives dichotomous variables
- `cut`: if dichotomous = TRUE, then items with values > cut are assigned 1, otherwise 0.

**Value**

a `ncases` x `nvariables` matrix

**Author(s)**

William Revelle

**See Also**

`VSS`, `ICLUST`

**Examples**

```r
## Not run:
simulated <- sim.VSS(1000,20,4,.6)
vss <- VSS(simulated,rotate="varimax")
VSS.plot(vss)

## End(Not run)
```
Description

Rotations of factor analysis and principal components analysis solutions typically try to represent correlation matrices as simple structured. An alternative structure, appealing to some, is a circumplex structure where the variables are uniformly spaced on the perimeter of a circle in a two dimensional space. Generating these data is straightforward, and is useful for exploring alternative solutions to affect and personality structure.

Usage

```r
simulation.circ(samplesize=c(100,200,400,800), numberofvariables=c(16,32,48,72))
circ.sim.plot(x.df)
```

Arguments

- `samplesize` a vector of sample sizes to simulate
- `numberofvariables` vector of the number of variables to simulate
- `x.df` A data frame resulting from `simulation.circ`

Details

"A common model for representing psychological data is simple structure (Thurstone, 1947). According to one common interpretation, data are simple structured when items or scales have non-zero factor loadings on one and only one factor (Revelle & Rocklin, 1979). Despite the commonplace application of simple structure, some psychological models are defined by a lack of simple structure. Circumplexes (Guttman, 1954) are one kind of model in which simple structure is lacking.

"A number of elementary requirements can be teased out of the idea of circumplex structure. First, circumplex structure implies minimally that variables are interrelated; random noise does not a circumplex make. Second, circumplex structure implies that the domain in question is optimally represented by two and only two dimensions. Third, circumplex structure implies that variables do not group or clump along the two axes, as in simple structure, but rather that there are always interstitial variables between any orthogonal pair of axes (Saucier, 1992). In the ideal case, this quality will be reflected in equal spacing of variables along the circumference of the circle (Gurtman, 1994; Wiggins, Steiger, & Gaelick, 1981). Fourth, circumplex structure implies that variables have a constant radius from the center of the circle, which implies that all variables have equal communality on the two circumplex dimensions (Fisher, 1997; Gurtman, 1994). Fifth, circumplex structure implies that all rotations are equally good representations of the domain (Conte & Plutchik, 1981; Larsen & Diener, 1992)." (Acton and Revelle, 2004)

Acton and Revelle reviewed the effectiveness of 10 tests of circumplex structure and found that four did a particularly good job of discriminating circumplex structure from simple structure, or circumplexes from ellipsoidal structures. Unfortunately, their work was done in Pascal and is not easily available. Here we release R code to do the four most useful tests:

The Gap test of equal spacing
Fisher’s test of equality of axes
A test of indifference to Rotation

A test of equal Variance of squared factor loadings across arbitrary rotations.

Included in this set of functions are simple procedure to generate circumplex structured or simple structured data, the four test statistics, and a simple simulation showing the effectiveness of the four procedures.

circ.sim.plot compares the four tests for circumplex, ellipsoid and simple structure data as function of the number of variables and the sample size. What one can see from this plot is that although no one test is sufficient to discriminate these alternative structures, the set of four tests does a very good job of doing so. When testing a particular data set for structure, comparing the results of all four tests to the simulated data will give a good indication of the structural properties of the data.

Value

A data.frame with simulation results for circumplex, ellipsoid, and simple structure data sets for each of the four tests.

Note

The simulations default values are for sample sizes of 100, 200, 400, and 800 cases, with 16, 32, 48 and 72 items.

```
Find the Squared Multiple Correlation (SMC) of each variable with the remaining variables in a matrix

Description

The squared multiple correlation of a variable with the remaining variables in a matrix is sometimes used as initial estimates of the communality of a variable.

SMCs are also used when estimating reliability using Guttman’s lambda 6 coefficient. The SMC is just 1 - 1/diag(R.inv) where R.inv is the inverse of R.

Usage

smc(R, covar=FALSE)

Arguments

R

A correlation matrix or a dataframe. In the latter case, correlations are found.

covar

if covar = TRUE and R is either a covariance matrix or data frame, then return the smc * variance for each item

Value

a vector of squared multiple correlations. Or, if covar=TRUE, a vector of squared multiple correlations * the item variances

If the matrix is not invertible, then a vector of 1s is returned.

In the case of correlation or covariance matrices with some NAs, those variables with NAs are dropped and the SMC for the remaining variables are found. The missing SMCs are then estimated by finding the maximum correlation for that column (with a warning).

Description

Project Talent gave 440,000 US high school students a number of personality and ability tests. Of these, the data for 346,000 were available for followup. Subsequent followups were collected 11 and 50 years later. Marion Spengler and her colleagues Rodica Damian, and Brent Roberts reported on the stability and change across 50 years of personality and ability. Here is the correlation matrix of 25 of their variables (Spengler) as well as a slightly different set of 19 variables (Damian). This is a nice example of mediation and regression from a correlation matrix. (Temporarily copied from psychTools to pass CRAN checks.)

Usage

data("Damian")

Format

A 25 x 25 correlation matrix of demographic, personality, and ability variables, based upon 346,660 participants.

Race/Ethnicity 1 = other, 2 = white/caucasian
Sex 1 = Male, 2 = Female
Age Cohort = 9th grade, 10th grade, 11th grade, 12th grade
Parental Parental SES based upon 9 questions of home value, family income, etc.
IQ Standardized composite of Verbal, Spatial and Mathematical
Sociability etc. 10 scales based upon prior work by Damian and Roberts
Maturity A higher order factor from the prior 10 scales
Extraversion The second higher order factor
Interest Self reported interest in school
Reading Self report reading skills
Writing Self report writing skills
Responsible Self reported responsibility scale
Ed.11 Education level at 11 year followup
Educ.50 Education level at 50 year followup
OccPres.11 Occupational Prestige at 11 year followup
OccPres.50 Occupational Prestige at 50 year followup
Income.11 Income at 11 year followup
Income.50 Income at 50 year followup

Details

Data from Project Talent was collected in 1960 on a representative sample of American high school students. Subsequent follow up 11 and 50 years later are reported by Spengler et al (2018) and others.

spider
Make "radar" or "spider" plots.

Description
Radar plots and spider plots are just two of the many ways to show multivariate data. radar plots correlations as vectors ranging in length from 0 (corresponding to r=-1) to 1 (corresponding to an r=1). The vectors are arranged radially around a circle. Spider plots connect the end points of each vector. The plots are most appropriate if the variables are organized in some meaningful manner.

Usage
spider(y,x,data=NULL,labels=NULL,center=FALSE,connect=TRUE,overlay=FALSE,
rescale=FALSE,scale=1,ncolors=31,fill=FALSE,main=NULL,...)
radar(x,labels=NULL,center=FALSE,connect=FALSE,scale=1,ncolors=31,fill=FALSE,
add=FALSE,linetyp="solid", main="Radar Plot",...)

Arguments
y
The y variables to plot. Each y is plotted against all the x variables
x
The x variables defining each line. Each y is plotted against all the x variables
data
A correlation matrix from which the x and y variables are selected
labels
Labels (assumed to be colnames of the data matrix) for each x variable
rescale
If TRUE, then rescale the data to have mean 0 and sd = 1. This is used if plotting raw data rather than correlations.
spider

center if TRUE, then lines originate at the center of the plot, otherwise they start at the mid point.

connect if TRUE, a spider plot is drawn, if FALSE, just a radar plot

scale can be used to magnify the plot, to make small values appear larger.

ncolors if ncolors > 2, then positive correlations are plotted with shades of blue and negative correlations shades of red. This is particularly useful if fill is TRUE. ncolors should be an odd number, so that neutral values are coded as white.

fill if TRUE, fill the polygons with colors scaled to size of correlation

overlay If TRUE, plot multiple spiders on one plot, otherwise plot them as separate plots

add If TRUE, add a new spider diagram to the previous one.

linetyp see lty in the par options

main A label or set of labels for the plots

... Additional parameters can be passed to the underlying graphics call

Details

Displaying multivariate profiles may be done by a series of lines (see, e.g., matplot), by colors (see, e.g., cor.plot, or by radar or spider plots.

To show just one variable as a function of several others, use radar. To make multiple plots, use spider. An additional option when comparing just a few y values is to do overlay plots. Alternatively, set the plotting options to do several on one page.

Value

Either a spider or radar plot

Author(s)

William Revelle

Alternative estimates of test reliability

Description

Eight alternative estimates of test reliability include the six discussed by Guttman (1945), four discussed by ten Berge and Zergers (1978) ($\mu_0$,...,$\mu_3$) as well as $\beta$ (the worst split half, Revelle, 1979), the glb (greatest lowest bound) discussed by Bentler and Woodward (1980), and $\omega_h$ and $\omega_t$ (McDonald, 1999; Zinbarg et al., 2005). Greatest and lowest split-half values are found by brute force or sampling.

Usage

```r
splitHalf(r, raw=FALSE, brute=FALSE, n.sample=10000, covar=FALSE, check.keys=TRUE, key=NULL, ci=.05, use="pairwise")
guttman(r, key=NULL)
tenberge(r)
glb(r, key=NULL)
glb.fa(r, key=NULL)
```

Arguments

- `r`: A correlation or covariance matrix or raw data matrix.
- `raw`: return a vector of split half reliabilities
- `brute`: Use brute force to try all combinations of n take n/2.
- `n.sample`: if brute is false, how many samples of split halves should be tried?
- `covar`: Should the covariances or correlations be used for reliability calculations
- `check.keys`: If TRUE, any item with a negative loading on the first factor will be flipped in sign
- `key`: a vector of -1, 0, 1 to select or reverse key items. See if the key vector is less than the number of variables, then item numbers to be reverse can be specified.
- `use`: Should we find the correlations using "pairwise" or "complete" (see ?cor)
- `ci`: The alpha level to use for the confidence intervals of the split half estimates

Details

Surprisingly, more than a century after Spearman (1904) introduced the concept of reliability to psychologists, there are still multiple approaches for measuring it. Although very popular, Cronbach’s $\alpha$ (1951) underestimates the reliability of a test and over estimates the first factor saturation. Using `splitHalf` for tests with 16 or fewer items, all possible splits may be found fairly easily. For tests with 17 or more items, n.sample splits are randomly found. Thus, for 16 or fewer items, the upper and lower bounds are precise. For 17 or more items, they are close but will probably slightly underestimate the highest and overestimate the lowest reliabilities.

The guttman function includes the six estimates discussed by Guttman (1945), four of ten Berge and Zergers (1978), as well as Revelle’s $\beta$ (1979) using `splitHalf`. The companion function, `omega` calculates omega hierarchical ($\omega_h$) and omega total ($\omega_t$).
Guttman’s first estimate $\lambda_1$ assumes that all the variance of an item is error:

$$\lambda_1 = 1 - \frac{\text{tr}(\mathbf{V}_x)}{V_x} = \frac{V_x - \text{tr}(\mathbf{V}_x)}{V_x}$$

This is a clear underestimate.

The second bound, $\lambda_2$, replaces the diagonal with a function of the square root of the sums of squares of the off diagonal elements. Let $C_2 = \mathbf{1}(\mathbf{V} - \text{diag}(\mathbf{V}))^2\mathbf{1}$, then

$$\lambda_2 = \lambda_1 + \frac{\sqrt{\sum_{h=1}^{n-1} C_2}}{V_x} = \frac{V_x - \text{tr}(\mathbf{V}_x) + \sqrt{\sum_{h=1}^{n-1} C_2}}{V_x}$$

Effectively, this is replacing the diagonal with $n \times$ the square root of the average squared off diagonal element.

Guttman’s 3rd lower bound, $\lambda_3$, also modifies $\lambda_1$ and estimates the true variance of each item as the average covariance between items and is, of course, the same as Cronbach’s $\alpha$.

$$\lambda_3 = \lambda_1 + \frac{V_x - \text{tr}(\mathbf{V}_x)}{n(n-1)} = \frac{n\lambda_1}{n-1} = \frac{n}{n-1} \left( 1 - \frac{\text{tr}(\mathbf{V}_x)}{V_x} \right) = \frac{n}{n-1} \frac{V_x - \text{tr}(\mathbf{V}_x)}{V_x} = \alpha$$

This is just replacing the diagonal elements with the average off diagonal elements. $\lambda_2 \geq \lambda_3$ with $\lambda_2 > \lambda_3$ if the covariances are not identical.

$\lambda_3$ and $\lambda_2$ are both corrections to $\lambda_1$ and this correction may be generalized as an infinite set of successive improvements. (Ten Berge and Zegers, 1978)

$$\mu_r = \frac{1}{V_x} (p_0 + (p_1 + (p_2 + \ldots + (p_{r-1} + (p_r)^{1/2})^{1/2})^{1/2})^{1/2}), r = 0, 1, 2, \ldots$$

where

$$p_h = \sum_{i \neq j} \sigma_{ij}^2, h = 0, 1, 2, \ldots r - 1$$

and

$$p_h = \frac{n}{n-1} \sigma_{ij}^2, h = r$$

tenberge and Zegers (1978). Clearly $\mu_0 = \lambda_3 = \alpha$ and $\mu_1 = \lambda_2$. $\mu_r \geq \mu_{r-1} \geq \ldots \mu_1 \geq \mu_0$, although the series does not improve much after the first two steps.

Guttman’s fourth lower bound, $\lambda_4$ was originally proposed as any split half reliability but has been interpreted as the greatest split half reliability. If $X$ is split into two parts, $X_a$ and $X_b$, with correlation $r_{ab}$ then

$$\lambda_4 = 2 \left( 1 - \frac{V_{X_a} + V_{X_b}}{V_X} \right) = \frac{4r_{ab}}{V_X} = \frac{4r_{ab}}{V_{X_a} + V_{X_b} + 2r_{ab}V_{X_a}V_{X_b}}$$

which is just the normal split half reliability, but in this case, of the most similar splits. For 16 or fewer items, this is found by trying all possible splits. For 17 or more items, this is estimated by taking n.sample random splits.

$\lambda_5$, Guttman’s fifth lower bound, replaces the diagonal values with twice the square root of the maximum (across items) of the sums of squared interitem covariances

$$\lambda_5 = \lambda_1 + \frac{2\sqrt{C_2}}{V_X}$$
Although superior to $\lambda_1$, $\lambda_5$ underestimates the correction to the diagonal. A better estimate would be analogous to the correction used in $\lambda_3$:

$$\lambda_{5+} = \lambda_1 + \frac{n}{n - 1} \frac{2\sqrt{C_2}}{V_x}.$$ 

$\lambda_6$, Guttman’s final bound considers the amount of variance in each item that can be accounted for the linear regression of all of the other items (the squared multiple correlation or smc), or more precisely, the variance of the errors, $e_j^2$, and is

$$\lambda_6 = 1 - \frac{\sum e_j^2}{V_x} = 1 - \frac{\sum (1 - r_{smc}^2)}{V_x}.$$ 

The smc is found from all the items. A modification to Guttman $\lambda_6$, $\lambda_6^*$ reported by the score.items function is to find the smc from the entire pool of items given, not just the items on the selected scale.

Guttman’s $\lambda_4$ is the greatest split half reliability. Although originally found here by combining the output from three different approaches, this has now been replaced by using splitHalf to find the maximum value by brute force (for 16 or fewer items) or by taking a substantial number of random splits.

The algorithms that had been tried before included:

a) Do an ICLUST of the reversed correlation matrix. ICLUST normally forms the most distinct clusters. By reversing the correlations, it will tend to find the most related clusters. Truly a weird approach but tends to work.

b) Alternatively, a kmeans clustering of the correlations (with the diagonal replaced with 0 to make pseudo distances) can produce 2 similar clusters.

c) Clusters identified by assigning items to two clusters based upon their order on the first principal factor. (Highest to cluster 1, next 2 to cluster 2, etc.)

These three procedures will produce keys vectors for assigning items to the two splits. The maximum split half reliability is found by taking the maximum of these three approaches. This is not elegant but is fast.

The brute force and the sampling procedures seem to provide more stable and larger estimates.

Yet another procedure, implemented in splitHalf is actually form all possible (for n items <= 16) or sample 10,000 (or more) split halves corrected for test length. This function returns the best and worst splits as item keys that can be used for scoring purposes, if desired. Can do up to 24 items in reasonable time, but gets much slower for more than about 24 items.

There are three greatest lower bound functions. One, glb finds the greatest split half reliability, $\lambda_4$. This considers the test as set of items and examines how best to partition the items into splits. The other two, glb.fa and glb.algebraic, are alternative ways of weighting the diagonal of the matrix. glb.fa estimates the communalities of the variables from a factor model where the number of factors is the number with positive eigen values. Then reliability is found by

$$glb = 1 - \frac{\sum e_j^2}{V_x} = 1 - \frac{\sum (1 - h^2)}{V_x}.$$ 

This estimate will differ slightly from that found by glb.algebraic, written by Andreas Moeltner which uses calls to csdp in the Rcsdp package. His algorithm, which more closely matches the
description of the glb by Jackson and Woodhouse, seems to have a positive bias (i.e., will over estimate the reliability of some items; they are said to be \( = 1 \)) for small sample sizes. More exploration of these two algorithms is underway.

Compared to `glb_algebraic`, `glb.fa` seems to have less (positive) bias for smallish sample sizes \((n < 500)\) but larger for large \((> 1000)\) sample sizes. This interacts with the number of variables so that equal bias sample size differs as a function of the number of variables. The differences are, however small. As samples sizes grow, `glb_algebraic` seems to converge on the population value while `glb.fa` has a positive bias.

statsBy

Find statistics (including correlations) within and between groups for basic multilevel analyses

Description

When examining data at two levels (e.g., the individual and by some set of grouping variables), it is useful to find basic descriptive statistics (means, sds, ns per group, within group correlations) as well as between group statistics (over all descriptive statistics, and overall between group correlations). Of particular use is the ability to decompose a matrix of correlations at the individual level into correlations within group and correlations between groups.

Usage

statsBy(data, group, cors = FALSE, cor="cor", method="pearson", use="pairwise", poly=FALSE, na.rm=TRUE, alpha=.05,minlength=5)
statsBy.boot(data,group,ntrials=10,cors=FALSE,replace=TRUE,method="pearson")
statsBy.boot.summary(res.list,var="ICC2")
faBy(stats, nfactors = 1, rotate = "oblimin", fm = "minres", free = TRUE, all=FALSE, min.n = 12,quant=.1, ...)

Arguments

data A matrix or dataframe with rows for subjects, columns for variables. One of these columns should be the values of a grouping variable.
group The names or numbers of the variable in data to use as the grouping variables.
cors Should the results include the correlation matrix within each group? Default is FALSE.
cor Type of correlation/covariance to find within groups and between groups. The default is Pearson correlation. To find within and between covariances, set cor="cov". Although polychoric, tetrachoric, and mixed correlations can be found within groups, this does not make sense for the between groups or the pooled within groups. In this case, correlations for each group will be as specified, but the between groups and pooled within will be Pearson. See the discussion below.
method What kind of correlations should be found (default is Pearson product moment)
use How to treat missing data. use="pairwise" is the default
poly Find polychoric,tetrachoric correlations within groups if requested.
na.rm Should missing values be deleted (na.rm=TRUE) or should we assume the data clean?
alpha
The alpha level for the confidence intervals for the ICC1 and ICC2, and rWG, rBG.

minlength
The minimum length to use when abbreviating the labels for confidence intervals.

ntrials
The number of trials to run when bootstrapping statistics.

replace
Should the bootstrap be done by permuting the data (replace=FALSE) or sampling with replacement (replace=TRUE).

res.list
The results from statsBy.boot may be summarized using boot.stats.

var
Name of the variable to be summarized from statsBy.boot.

stats
The output of statsBy.

nfactors
The number of factors to extract in each subgroup.

rotate
The factor rotation/transformation.

fm
The factor method (see fa for details).

free
Allow the factor solution to be freely estimated for each individual (see note).

all
Report individual factor analyses for each group as well as the summary table.

min.n
The minimum number of within subject cases before we factor analyze it.

quant
Show the upper and lower quant quantile of the factor loadings in faBy.

... Other parameters to pass to the fa function.

Details
Multilevel data are endemic in psychological research. In multilevel data, observations are taken on subjects who are nested within some higher level grouping variable. The data might be experimental (participants are nested within experimental conditions) or observational (students are nested within classrooms, students are nested within college majors.) To analyze this type of data, one uses random effects models or mixed effect models, or more generally, multilevel models. There are at least two very powerful packages (nlme and multilevel) which allow for complex analysis of hierarchical (multilevel) data structures. statsBy is a much simpler function to give some of the basic descriptive statistics for two level models. It is meant to supplement true multilevel modeling.

For a group variable (group) for a data.frame or matrix (data), basic descriptive statistics (mean, sd, n) as well as within group correlations (cors=TRUE) are found for each group.

The amount of variance associated with the grouping variable compared to the total variance is the type 1 IntraClass Correlation (ICC1):

$$ICC_1 = \frac{(MS_b - MS_w)}{(MS_b + MS_w \times (npr - 1))}$$

where npr is the average number of cases within each group.

The reliability of the group differences may be found by the ICC2 which reflects how different the means are with respect to the within group variability.

$$ICC_2 = \frac{(MS_b - MS_w)/MS_b}.$$ Because the mean square between is sensitive to sample size, this estimate will also reflect sample size.

Perhaps the most useful part of statsBy is that it decomposes the observed correlations between variables into two parts: the within group and the between group correlation. This follows the decomposition of an observed correlation into the pooled correlation within groups (rWG) and the weighted correlation of the means between groups discussed by Pedazur (1997) and by Bliese in the multilevel package.

$$r_{xy} = \eta x_{ug} \ast \eta y_{ug} \ast r_{xyug} + \eta x_{bg} \ast \eta y_{bg} \ast r_{xybg}$$

where $$r_{xy}$$ is the normal correlation which may be decomposed into a within group and between group correlations $$r_{xyug}$$ and $$r_{xybg}$$ and $$\eta$$ is the correlation of the data with the within group values, or the group means.

It is important to realize that the within group and between group correlations are independent of each other. That is to say, inferring from the ”ecological correlation” (between groups) to the lower
level (within group) correlation is inappropriate. However, these between group correlations are still very meaningful, if inferences are made at the higher level.

There are actually two ways of finding the within group correlations pooled across groups. We can find the correlations within every group, weight these by the sample size and then report this pooled value (pooled). This is found if the cors option is set to TRUE. It is logically equivalent to doing a sample size weighted meta-analytic correlation. The other way, rwg, considers the covariances, variances, and thus correlations when each subject’s scores are given as deviation score from the group mean.

If finding tetrachoric, polychoric, or mixed correlations, these two estimates will differ, for the pooled value is the weighted polychoric correlation, but the rwg is the Pearson correlation.

Confidence values and significance of \( r_{xywg} \), \( pwg \), reflect the pooled number of cases within groups, while \( r_{xybg} \), \( pbg \), the number of groups. These are not corrected for multiple comparisons.

withinBetween is an example data set of the mixture of within and between group correlations. sim.multilevel will generate simulated data with a multilevel structure.

The statsBy.boot function will randomize the grouping variable ntrials times and find the statsBy output. This can take a long time and will produce a great deal of output. This output can then be summarized for relevant variables using the statsBy.boot.summary function specifying the variable of interest. These two functions are useful in order to find if the mere act of grouping leads to large between group correlations.

Consider the case of the relationship between various tests of ability when the data are grouped by level of education (statsBy(sat.act,"education")) or when affect data are analyzed within and between an affect manipulation (statsBy(flat,group="Film") ). Note in this latter example, that because subjects were randomly assigned to Film condition for the pretest, that the pretest ICC1s cluster around 0.

faBy uses the output of statsBy to perform a factor analysis on the correlation matrix within each group. If the free parameter is FALSE, then each solution is rotated towards the group solution (as much as possible). The output is a list of each factor solution, as well as a summary matrix of loadings and interfactor correlations for all groups.

Value

- **means**: The means for each group for each variable.
- **sd**: The standard deviations for each group for each variable.
- **n**: The number of cases for each group and for each variable.
- **ICC1**: The intraclass correlation reflects the amount of total variance associated with the grouping variable.
- **ICC2**: The intraclass correlation (2) reflecting how much the groups means differ.
- **ci1**: The confidence intervals for the ICC1
- **ci2**: The confidence intervals for the ICC2
- **F**: The F from a one-way anova of group means.
- **rwg**: The pooled within group correlations.
- **ci.wg**: The confidence intervals of the pooled within group correlations.
- **rbg**: The sample size weighted between group correlations.
- **c.bg**: The confidence intervals of the rbg values
- **etawg**: The correlation of the data with the within group values.
- **etabg**: The correlation of the data with the group means.
statsBy

pb

The probability of the between group correlation

pw

The probability of the within group correlation

r

In the case that we want the correlations in each group, r is a list of the within group correlations for every group. Set cors=TRUE

within

is just another way of displaying these correlations. within is a matrix which reports the lower off diagonal correlations as one row for each group.

pooled

The sample size weighted correlations. This is just within weighted by the sample sizes. The cors option must be set to TRUE to get this. See the note.

Note

If finding polychoric correlations, the two estimates of the pooled within group correlations will differ, for the pooled value is the weighted polychoric correlation, but the rwg is the Pearson correlation.

The value of rb is the group size weighted correlation. This is not the same as just finding the correlation of the group means (i.e. cor(means)).

The statsBy.boot function will sometimes fail if sampling with replacement because if the group sizes differ drastically, some groups will be empty. In this case, sample without replacement.

The statsBy.boot function can take a long time. (As I am writing this, I am running 1000 replications of a problem with 64,000 cases and 84 groups. It is taking about 3 seconds per replication on a MacBook Pro.)

The faBy function takes the output of statsBy (with the cors=TRUE option) and then factors each individual subject. By default, the solutions are organized so that the factors “match” the group solution in terms of their order. It is also possible to attempt to force the solutions to match by order and also by using the TargetQ rotation function. (free=FALSE)

structure.diagram

Draw a structural equation model specified by two measurement models and a structural model

Description

Graphic presentations of structural equation models are a very useful way to conceptualize SEM and confirmatory factor models. Given a measurement model on x (xmodel) and on y (ymodel) as well as a path model connecting x and y (phi), draw the graph. If the ymodel is not specified, just draw the measurement model (xmodel + phi). If the Rx or Ry matrices are specified, show the correlations between the x variables, or y variables.

Perhaps even more usefully, the function returns a model appropriate for running directly in the SEM package written by John Fox or the lavaan package by Yves Rosseel. For this option to work directly, it is necessary to specify that errors=TRUE.

Input can be specified as matrices or the output from fa, factanal, or a rotation package such as GPArotation.

For symbolic graphs, the input matrices can be character strings or mixtures of character strings and numeric vectors.

As an option, for those without Rgraphviz installed, structure.sem will just create the SEM model and skip the graph. (This functionality is now included in structure.diagram.)

structure.diagram will draw the diagram without using Rgraphviz and is probably the preferred option. structure.graph will be removed eventually.

lavaan.diagram will draw either cfa or sem results from the lavaan package. It has been tested for cfa, sem and mimic type output. It takes the output object from lavaan and then calls structure.diagram.

Usage

structure.diagram(fx, Phi=NULL, fy=NULL, labels=NULL, cut=.3, errors=FALSE, simple=TRUE, regression=FALSE, lr=TRUE, Rx=NULL, Ry=NULL, digits=1, e.size=.1, main="Structural model", ...)
structure.graph(fx, Phi = NULL, fy = NULL, out.file = NULL, labels = NULL, cut = 0.3, errors = TRUE, simple = TRUE, regression = FALSE, size = c(8, 6), node.font = c("Helvetica", 14), edge.font = c("Helvetica", 10), rank.direction = c("RL", "TB", "LR", "BT"), digits = 1, title = "Structural model", ...)
structure.sem(fx, Phi = NULL, fy = NULL, out.file = NULL, labels = NULL, cut = 0.3, errors = TRUE, simple = TRUE, regression = FALSE)
lavaan.diagram(fit, main, e.size=.1,...)
sem.diagram(fit, main="A SEM from the sem package",...)
sem.graph(fit, out.file=NULL, main = "A SEM from the sem package",...)

# Be careful with the naming of the main argument in the calls.
# For example, structure.sem requires main=TRUE or main="Structural model" whereas all the other
# functions require main=FALSE or main=TRUE without quotes.

# As an option, for those without Rgraphviz installed, structure.sem will just create the model and skip the graph.
structure.diagram

Arguments

fx   a factor model on the x variables.
Phi  A matrix of directed relationships. Lower diagonal values are drawn. If the
     upper diagonal values match the lower diagonal, two headed arrows are drawn.
     For a single, directed path, just the value may be specified.
fy   a factor model on the y variables (can be empty)
Rx   The correlation matrix among the x variables
Ry   The correlation matrix among the y variables
out.file  name a file to send dot language instructions.
labels  variable labels if not specified as colnames for the matrices
cut   Draw paths for values > cut
fit    The output from a lavaan cfa or sem
errors draw an error term for observerd variables
simple Just draw one path per x or y variable
regression Draw a regression diagram (observed variables cause Y)
lr    Direction of diagram is from left to right (lr=TRUE, default) or from bottom to
      top (lr=FALSE)
e.size  size of the ellipses in structure.diagram
main   main title of diagram
size   page size of graphic
node.font  font type for graph
edge.font  font type for graph
rank.direction Which direction should the graph be oriented
digits  Number of digits to draw
title   Title of graphic
...    other options to pass to Rgraphviz

Details

The recommended function is structure.diagram which does not use Rgraphviz but which does not
produce dot code either.

All three structure function return a matrix of commands suitable for using in the sem or lavaan
packages. (Specify errors=TRUE to get code that will run directly in the sem package.)

The structure.graph output can be directed to an output file for post processing using the dot graphic
language but requires that Rgraphviz is installed.

lavaan.diagram will create sem, cfa, or mimic diagrams depending upon the lavaan input.

sem.diagram and sem.graph convert the output from a simple CFA done with the sem package and
draw them using structure.diagram or structure.graph. lavaan.diagram converts the output (fit) from
a simple CFA done with the lavaan package and draws them using structure.diagram. The figure is
organized to show the appropriate paths between:

The correlations between the X variables (if Rx is specified)
The X variables and their latent factors (if fx is specified)
The latent X and the latent Y (if Phi is specified)
The latent Y and the observed Y (if fy is specified)
The correlations between the Y variables (if Ry is specified)

A confirmatory factor model would specify just fx and Phi, a structural model would include fx, Phi, and fy. The raw correlations could be shown by just including Rx and Ry.

lavaan.diagram may be called from the diagram function which also will call fa.diagram, omega.diagram or iclust.diagram, depending upon the class of the fit.

Other diagram functions include fa.diagram, omega.diagram. All of these functions use the various dia functions such as dia.rect, dia.ellipse, dia.arrow, dia.curve, dia.curved.arrow, and dia.shape.

Value

sem (invisible) a model matrix (partially) ready for input to John Fox’s sem package. It is of class “mod” for prettier output.
lavaan (invisible) A model specification for the lavaan package.
dotfile If out.file is specified, a dot language file suitable for using in a dot graphics program such as graphviz or Omnigraffle.

A graphic structural diagram in the graphics window

#and a really messy regression model
x8 <- c("b1","b2","b3")
r8 <- matrix(c(1,"r12","r13","r12",1,"r23","r13","r23",1),ncol=3)
structure.list

Create factor model matrices from an input list

Description

When creating a structural diagram or a structural model, it is convenient to not have to specify all of the zero loadings in a structural matrix. structure.list converts list input into a design matrix. phi.list does the same for a correlation matrix. Factors with NULL values are filled with 0s.

Usage

structure.list(nvars, f.list, f=NULL, f.labels = NULL, item.labels = NULL)
phi.list(nf, f.list, f.labels = NULL)

Arguments

nvars Number of variables in the design matrix
f.list A list of items included in each factor (for structure.list, or the factors that correlate with the specified factor for phi.list)
f prefix for parameters – needed in case of creating an X set and a Y set
f.labels Names for the factors
item.labels Item labels
nf Number of factors in the phi matrix

Details

This is almost self explanatory. See the examples.

Value

factor.matrix a matrix of factor loadings to model

See Also

structure.graph for drawing it, or sim.structure for creating this data structure.

Examples

fx <- structure.list(9, list(F1=c(1,2,3), F2=c(4,5,6), F3=c(7,8,9)))
fy <- structure.list(3, list(Y=c(1,2,3), "Y"))
phi <- phi.list(4, list(F1=c(4), F2=c(1,4), F3=c(2), F4=c(1,2,3)))
fx
phi
fy
Form a super matrix from two sub matrices.

### Description
Given the matrices nXm, and jYk, form the super matrix of dimensions (n+j) and (m+k) with elements x and y along the super diagonal. Useful when considering structural equations. The measurement models x and y can be combined into a larger measurement model of all of the variables. If either x or y is a list of matrices, then recursively form a super matrix of all of those elements.

### Usage

```r
superMatrix(x, y)
super.matrix(x, y)  # Deprecated
```

### Arguments

- **x**: A n x m matrix or a list of such matrices
- **y**: A j x k matrix or a list of such matrices

### Details
Several functions, e.g., `sim.structural`, `structure.graph`, `make.keys` use matrices that can be thought of as formed from a set of submatrices. In particular, when using `make.keys` in order to score a set of items (`scoreItems` or `scoreOverlap`) or to form specified clusters (`cluster.cor`), it is convenient to define different sets of scoring keys for different sets of items and to combine these scoring keys into one super key.

### Value
A (n+j) x (m+k) matrix with appropriate row and column names

### Author(s)
William Revelle

### See Also
`sim.structural`, `structure.graph`, `make.keys`

### Examples

```r
mx <- matrix(c(0.9, 0.8, 0.7, rep(0, 4), 0.8, 0.7, 0.6), ncol=2)
my <- matrix(c(0.6, 0.5, 0.4))
colnames(mx) <- paste("X", 1:dim(mx)[2], sep="")
rownames(mx) <- paste("Xv", 1:dim(mx)[1], sep="")
colnames(my) <- "Y"
rownames(my) <- paste("Yv", 1:3, sep="")
mxy <- superMatrix(mx, my)
# show the use of a list to do this as well
```
key1 <- make.keys(6,list(first=c(1,-2,3),second=4:6,all=1:6)) #make a scoring key
key2 <- make.keys(4,list(EA=c(1,2),TA=c(3,4)))
superMatrix(list(key1,key2))

`table2matrix`  
Convert a table with counts to a matrix or data.frame representing those counts.

**Description**

Some historical sets are reported as summary tables of counts in a limited number of bins. Transforming these tables to data.frames representing the original values is useful for pedagogical purposes. (E.g., transforming the original Galton table of height x cubits in order to demonstrate regression.) The column and row names must be able to be converted to numeric values.

**Usage**

```r
table2matrix(x, labs = NULL)  
table2df(x, count=NULL,labs = NULL)
```

**Arguments**

- `x`  
  A two dimensional table of counts with row and column names that can be converted to numeric values.

- `count`  
  if present, then duplicate each row count times

- `labs`  
  Labels for the rows and columns. These will be used for the names of the two columns of the resulting matrix

**Details**

The original Galton (1888) of heights by cubits (arm length) is in tabular form. To show this as a correlation or as a scatter plot, it is useful to convert the table to a matrix or data frame of two columns.

This function may also be used to convert an item response pattern table into a data table. e.g., the Bock data set `bock`.

**Value**

A matrix (or data.frame) of sum(x) rows and two columns.

**Author(s)**

William Revelle

data(cubits)
cubit <- table2matrix(psychTools::cubits,labs=c("height","cubit"))
describe(cubit)
ellipses(cubit,n=1)
data(bock)
responses <- table2df(bock.table[,2:6],count=bock.table[,7],labs= paste("lsat6","1:5",sep=""))
describe(responses)

Description

Nurit Tal-Or, Jonanthon Cohen, Yariv Tasfati, and Albert Gunther (2010) examined the presumed effect of media on other people and change in attitudes. This data set is from Study 2, and examined the effect of presumed influence of the media upon subsequent actions. It is used as an example of mediation by Hayes (2013) and for the mediate function.

Usage

data("Tal.Or")

Format

A data frame with 123 observations on the following 6 variables.

<table>
<thead>
<tr>
<th>Variable</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>cond</td>
<td>Experimental Condition: 0 low media importance, 1 high media importance</td>
</tr>
<tr>
<td>pmi</td>
<td>Presumed media influence (based upon the mean of two items)</td>
</tr>
<tr>
<td>import</td>
<td>Importance of the issue</td>
</tr>
<tr>
<td>reaction</td>
<td>Subjects rated agreement about possible reactions to the story (mean of 4 items).</td>
</tr>
<tr>
<td>gender</td>
<td>1 = male, 2 = female</td>
</tr>
<tr>
<td>age</td>
<td>a numeric vector</td>
</tr>
</tbody>
</table>

Details

Tal-Or et al. (2010) examined the presumed effect of the media in two experimental studies. These data are from study 2. ‘... perceptions regarding the influence of a news story about an expected shortage in sugar were manipulated indirectly, by manipulating the perceived exposure to the news story, and behavioral intentions resulting from the story were consequently measured.’ (p 801).

Source

The data were downloaded from the webpages of Andrew Hayes (https://www.afhayes.com/public/hayes2018data.zip) supporting the first and second edition of his book. The name of the original data set was pmi. (Gender was recoded to reflect the number of X chromosomes).

The original data are from Nurit Tal-Or, Jonathan Cohen, Yariv Tsfati, and Albert C. Gunther and are used with their kind permission.

Examples

data(Tal.Or)
mediate(reaction ~ cond + (pmi), data = Tal.Or, n.iter=50)

Description

Item Response Theory provides a number of alternative ways of estimating latent scores. Here we compare 6 different ways to estimate the latent variable associated with a pattern of responses. Originally developed as a test for scoreIrt, but perhaps useful for demonstration purposes. Items are simulated using sim.irt and then scored using factor scores from factor.scores using statistics found using irt.fa, simple weighted models for 1 and 2 PL and 2 PN. Results show almost perfect agreement with estimates from MIRT and ltm for the dichotomous case and with MIRT for the polytomous case. (Results from ltm are unstable for the polytomous case, sometimes agreeing with scoreIrt and MIRT, sometimes being much worse.)

Usage

test.irt(nvar = 9, n.obs = 1000, mod = "logistic", type="tetra", low = -3, high = 3, seed = NULL)

Arguments

nvar Number of variables to create (simulate) and score
n.obs Number of simulated subjects
mod "logistic" or "normal" theory data are generated
type "tetra" for dichotomous, "poly" for polytomous
low items range from low to high
high items range from low to high
seed Set the random number seed using some non-nul value. Otherwise, use the existing sequence of random numbers

Details

n.obs observations (0/1) on nvar variables are simulated using either a logistic or normal theory model. Then, a number of different scoring algorithms are applied and shown graphically. Requires the ltm package to be installed to compare ltm scores.
Value

A dataframe of scores as well as the generating theta true score. A graphic display of the correlations is also shown.

test.psych Testing of functions in the psych package

Description

Test to make sure the psych functions run on basic test data sets

Usage

test.psych(first=1, last=5, short=TRUE, all=FALSE, fapc=FALSE)

Arguments

first first=1: start with dataset first
last last=5: test for datasets until last
short short=TRUE - don't return any analyses
all To get around a failure on certain Solaris 32 bit systems, all=FALSE is the default
fapc if fapc=TRUE, then do a whole series of tests of factor and principal component extraction and rotations.

Details

When modifying the psych package, it is useful to make sure that adding some code does not break something else. The test.psych function tests the major functions on various standard data sets. It also shows off a number of the capabilities of the psych package.

Uses 5 standard data sets:
USArrests Violent Crime Rates by US State (4 variables)
attitude The Chatterjee-Price Attitude Data
Harman23.cor$cov Harman Example 2.3 8 physical measurements
Harman74.cor$cov Harman Example 7.4 24 mental measurements
ability.cov$cov 8 Ability and Intelligence Tests

It also uses the bfi and ability data sets from psych
Value

if short=FALSE, then list of the output from all functions tested

Warning

Warning messages will be thrown by fa.parallel and sometimes by fa for random datasets.

Note

Although test.psych may be used as a quick demo of the various functions in the psych package, in general, it is better to try the specific functions themselves. The main purpose of test.psych is to make sure functions throw error messages or correct for weird conditions.

The datasets tested are part of the standard R data sets and represent some of the basic problems encountered.

When version 1.1.10 was released, it caused errors when compiling and testing on some Solaris 32 bit systems. The all option was added to avoid this problem (since I can’t replicate the problem on Macs or PCs). all=TRUE adds one more test, for a non-positive definite matrix.

#  f3 <- fa(bfi[1:15],3,n.iter=5,rotate="Promax")
#  fpoly <- fa(bfi[1:10],2,n.iter=5,cor="poly")
#  f1 <- fa(psychTools::ability,n.iter=4)
#  f1p <- fa(psychTools::ability,n.iter=4,cor="tet")
```
testRetest

Find various test-retest statistics, including test, person and item reliability

Description

Given two presentations of a test, it is straightforward to find the test-retest reliability, as well as the item reliability and person stability across items. Using the multi-level structure of the data, it is also possible to do a variance decomposition to find variance components for people, items, time, people x time, people x items, and items x time as well as the residual variance. This leads to various generalizability coefficients.

Usage

testRetest(t1,t2=NULL,keys=NULL,id="id", time= "time", select=NULL, check.keys=TRUE, warnings=TRUE,lmer=TRUE)

Arguments

t1 a data.frame or matrix for the first time of measurement.
t2 a data.frame or matrix for the second time of measurement. May be NULL if time is specified in t1
keys item names (or locations) to analyze, preface by "-" to reverse score.
id subject identification codes to match across time
time The name of the time variable identifying time 1 or 2 if just one data set is supplied.
select A subset of items to analyze
check.keys If TRUE will automatically reverse items based upon their correlation with the first principal component. Will throw a warning when doing so, but some people seem to miss this kind of message.
warnings If TRUE, then warn when items are reverse scored
lmer If TRUE, include the lmer variance decomposition. By default, this is true, but this can lead to long times for large data sets.

Details

There are many ways of measuring reliability. Test - Retest is one way. If the time interval is very short (or immediate), this is known as a dependability correlation, if the time interval is longer, a stability coefficient. In all cases, this is a correlation between two measures at different time points. Given the multi-level nature of these data, it is possible to find variance components associated with individuals, time, item, and time by item, etc. This leads to several different estimates of reliability (see multilevel.reliability for a discussion and references).

It is also possible to find the subject reliability across time (this is the correlation across the items at time 1 with time 2 for each subject). This is a sign of subject reliability (Wood et al, 2017). Items can show differing amounts of test-retest reliability over time. Unfortunately, the within person correlation has problems if people do not differ very much across items. If all items are in the same keyed direction, and measuring the same construct, then the response profile for an individual is essentially flat. This implies that the even with almost perfect reproducibility, that the correlation
can actually be negative. The within person distance (d2) across items is just the mean of the squared differences for each item. Although highly negatively correlated with the rqq score, this does distinguish between random responders (high dqq and low rqq) from consistent responders with lower variance (low dqq and low rqq).

Several individual statistics are reported in the scores object. These can be displayed by using pairs.panels for a graphic display of the relationship and ranges of the various measures.

Although meant to decompose the variance for tests with items nested within tests, if just given two tests, the variance components for people and for time will also be shown. The resulting variance ratio of people to total variance is the intraclass correlation between the two tests. See also ICC for the more general case.

Value

r12  The time 1 time 2 correlation of scaled scores across time
alpha  Guttman’s lambda 3 (aka alpha) and lambda 6* (item reliabilities based upon smcs) are found for the scales at times 1 and 2.
rqq  The within subject test retest reliability of response patterns over items
item.stats  Item reliabilities, item loadings at time 1 and 2, item means at time 1 and time 2
scores  A data frame of principal component scores at time 1 and time 2, raw scores from time 1 and time 2, the within person standard deviation for time 1 and time 2, and the rqq and dqq scores for each subject.
xy.df  If given separate t1 and t2 data.frames, this is combination suitable for using multilevel.reliability
key  A key vector showing which items have been reversed
ml  The multilevel output

Note

lmer=TRUE is the default and will do the variance decomposition using lmer. This will take some time. For 3032 cases with 10 items from the msqR and sai data set, this takes 92 seconds, but just .63 seconds if lmer = FALSE. For the 1895 subjects with repeated measures on the sai, it takes 85 seconds with lmer and .38 without out lmer.

In the case of just two tests (no items specified), the item based statistics (alpha, rqq, item.stats, scores, xy.df) are not reported.

Two examples are given. The first takes 200 cases from the sai data set. Subjects were given the 1ink[psychTools]{sai} twice with an intervening mood manipulation (four types of short film clips, with or without placebo/caffeine). The test retest stability of the sai are based upon the 20 sai items. The second example compares the scores of the 10 sai items that overlap with 10 items from the msqR data set from the same study. 1ink[psychTools]{sai} and msqR were given immediately after each other and although the format differs slightly, can be seen as measures of dependability.

Tetrachoric, polychoric, biserial and polyserial correlations from various types of input
Description

The tetrachoric correlation is the inferred Pearson Correlation from a two x two table with the assumption of bivariate normality. The polychoric correlation generalizes this to the n x m table. Particularly important when doing Item Response Theory or converting comorbidity statistics using normal theory to correlations. Input may be a 2 x 2 table of cell frequencies, a vector of cell frequencies, or a data.frame or matrix of dichotomous data (for tetrachoric) or of numeric data (for polychoric). The biserial correlation is between a continuous y variable and a dichotomous x variable, which is assumed to have resulted from a dichotomized normal variable. Biserial is a special case of the polychoric correlation, which is the inferred latent correlation between a continuous variable (X) and a ordered categorical variable (e.g., an item response). Input for these later two are data frames or matrices. Requires the mnormt package.

Usage

tetrachoric(x,y=NULL,correct=.5,smooth=TRUE,global=TRUE,weight=NULL,na.rm=TRUE, delete=TRUE)
polychoric(x,y=NULL,smooth=TRUE,global=TRUE,weight=NULL,correct=.5,progress=TRUE,na.rm=TRUE, delete=TRUE)
biserial(x,y)
polyserial(x,y)
polydi(p,d,taup,taud,global=TRUE,ML = FALSE, std.err = FALSE, weight=NULL,progress=TRUE,na.rm=TRUE,delete=TRUE,correct=.5)
#deprecated use polychoric instead
poly.mat(x, short = TRUE, std.err = FALSE, ML = FALSE)

Arguments

- **x**: The input may be in one of four forms:
  a) a data frame or matrix of dichotomous data (e.g., the lsat6 from the bock data set) or discrete numerical (i.e., not too many levels, e.g., the big 5 data set, bfi) for polychoric, or continuous for the case of biserial and polyserial.
  b) a 2 x 2 table of cell counts or cell frequencies (for tetrachoric) or an n x m table of cell counts (for both tetrachoric and polychoric).
  c) a vector with elements corresponding to the four cell frequencies (for tetrachoric)
  d) a vector with elements of the two marginal frequencies (row and column) and the comorbidity (for tetrachoric)

- **y**: A (matrix or dataframe) of discrete scores. In the case of tetrachoric, these should be dichotomous, for polychoric not too many levels, for biserial they should be discrete (e.g., item responses) with not too many (<10?) categories.

- **correct**: Correction value to use to correct for continuity in the case of zero entry cell for tetrachoric, polychoric, polybi, and mixed.cor. See the examples for the effect of correcting versus not correcting for continuity.

- **smooth**: if TRUE and if the tetrachoric/polychoric matrix is not positive definite, then apply a simple smoothing algorithm using cor.smooth.

- **global**: When finding pairwise correlations, should we use the global values of the tau parameter (which is somewhat faster), or the local values (global=FALSE)? The local option is equivalent to the polycor solution, or to doing one correlation at a time. global=TRUE borrows information for one item pair from the other pairs using those item’s frequencies. This will make a difference in the presence
of lots of missing data. With very small sample sizes with global=FALSE and correct=TRUE, the function will fail (for as yet underdetermined reasons.

**polycor**
A no longer used option, kept to stop other packages from breaking.

**weight**
A vector of length of the number of observations that specifies the weights to apply to each case. The NULL case is equivalent of weights of 1 for all cases.

**short**
short=TRUE, just show the correlations, short=FALSE give the full hetcor output from John Fox’s hetcor function if installed and if doing polychoric Deprecated

**std.err**
std.err=FALSE does not report the standard errors (faster) deprecated

**progress**
Show the progress bar (if not doing multicores)

**ML**
ML=FALSE do a quick two step procedure, ML=TRUE, do longer maximum likelihood — very slow! Deprecated

**na.rm**
Should missing data be deleted

**delete**
Cases with no variance are deleted with a warning before proceeding.

**p**
The polytomous input to polydi

**d**
The dichotomous input to polydi

**taup**
The tau values for the polytomous variables – if global=TRUE

**taud**
The tau values for the dichotomous variables – if global = TRUE

**Details**

Tetrachoric correlations infer a latent Pearson correlation from a two x two table of frequencies with the assumption of bivariate normality. The estimation procedure is two stage ML. Cell frequencies for each pair of items are found. In the case of tetrachorics, cells with zero counts are replaced with .5 as a correction for continuity (correct=TRUE).

The data typically will be a raw data matrix of responses to a questionnaire scored either true/false (tetrachoric) or with a limited number of responses (polychoric). In both cases, the marginal frequencies are converted to normal theory thresholds and the resulting table for each item pair is converted to the (inferred) latent Pearson correlation that would produce the observed cell frequencies with the observed marginals. (See draw.tetra and draw.cor for illustrations.)

This is a very computationally intensive function which can be speeded up considerably by using multiple cores and using the parallel package. The number of cores to use when doing polychoric or tetrachoric may be specified using the options command. The greatest step in speed is going from 1 core to 2. This is about a 50% savings. Going to 4 cores seems to have about at 66% savings, and 8 a 75% savings. The number of parallel processes defaults to 2 but can be modified by using the options command: options(“mc.cores”=4) will set the number of cores to 4.

The tetrachoric correlation is used in a variety of contexts, one important one being in Item Response Theory (IRT) analyses of test scores, a second in the conversion of comorbity statistics to correlation coefficients. It is in this second context that examples of the sensitivity of the coefficient to the cell frequencies becomes apparent:

**tetrachoric** and **polychoric** can find non-symmetric correlation matrices of set of x variables (columns) and y variable (rows). This is useful if extending a solution from a base set of items to a different set. See **fa.extension** for an application of this.

Consider the test data set from Kirk (1973) who reports the effectiveness of a ML algorithm for the tetrachoric correlation (see examples).

Examples include the lsat6 and lsat7 data sets in the **bock** data.
The polychoric function forms matrices of polychoric correlations by an local function (polyc) and will also report the tau values for each alternative. Earlier versions used John Fox’s polychor function which has now been replaced by the polyc function.

For finding one polychoric correlation from a table, see the Olsson example (below).

polychoric replaces poly.mat and is recommended. poly.mat was an alternative wrapper to the polycor function.

Biserial and polyserial correlations are the inferred latent correlations equivalent to the observed point-biserial and point-polyserial correlations (which are themselves just Pearson correlations).

The polychoric correlation is meant to work with matrix or dataframe input and treats missing data by finding the pairwise Pearson r corrected by the overall (all observed cases) probability of response frequency. This is particularly useful for SAPA procedures (https://sapa-project.org) (Revelle et al. 2010, 2016) with large amounts of missing data and no complete cases. See also the International Cognitive Ability Resource (https://icar-project.org) for similar data.

Ability tests and personality test matrices will typically have a cleaner structure when using tetrachoric or polychoric correlations than when using the normal Pearson correlation. However, if either alpha or omega is used to find the reliability, this will be an overestimate of the squared correlation of a latent variable the observed variable.

A biserial correlation (not to be confused with the point-biserial correlation which is just a Pearson correlation) is the latent correlation between x and y where y is continuous and x is dichotomous but assumed to represent an (unobserved) continuous normal variable. Let p = probability of x level 1, and q = 1 - p. Let zp = the normal ordinate of the z score associated with p. Then, 

\[ r_{bi} = r \cdot \sqrt{(pq)/zp} \]

The ‘ad hoc’ polyserial correlation, rps is just 

\[ r_{ps} = r \cdot \sqrt{(n-1)/n} \cdot \frac{\sigma_y}{\sum (zpi)} \]

where zpi are the ordinates of the normal curve at the normal equivalent of the cut point boundaries between the item responses. (Olsson, 1982)

All of these were inspired by (and adapted from) John Fox’s polychor package which should be used for precise ML estimates of the correlations. See, in particular, the hetcor function in the polychor package. The results from polychoric match the polychor answers to at least 5 decimals when using correct=FALSE, and global = FALSE.

For very small data sets, the correction for continuity for the polychoric correlations can lead to difficulties, particularly if using the global=FALSE option, or if doing just one correlation at a time. Setting a smaller correction value (i.e., correct = .1) seems to help.

John Uebersax (2015) makes the interesting point that both polychoric and tetrachoric correlations should be called latent correlations or latent continuous correlations because of the way they are found and not tetrachoric or polychoric which is the way they were found in the past. That is, what is the correlation between two latent variables that when artificially broken into two (tetrachoric) or more (polychoric) values produces the n x n table of observed frequencies.

For combinations of continuous, categorical, and dichotomous variables, see mixed.cor.

If using data with a variable number of response alternatives, it is necessary to use the global=FALSE option in polychoric.

For relatively small samples with dichotomous data if some cells are empty, or if the resampled matrices are not positive semi-definite, warnings are issued. this leads to serious problems if using multi.cores (the default if using a Mac). The solution seems to be to not use multi.cores (e.g., options(mc.cores =1)
**tetrachoric**

**Value**

<table>
<thead>
<tr>
<th>rho</th>
<th>The (matrix) of tetrachoric/polychoric/biserial correlations</th>
</tr>
</thead>
<tbody>
<tr>
<td>tau</td>
<td>The normal equivalent of the cutpoints</td>
</tr>
<tr>
<td>fixed</td>
<td>If any correlations were adjusted for continuity, the total number of adjustments will be reported.</td>
</tr>
</tbody>
</table>

**Note**

For tetrachoric, in the degenerate case of a cell entry with zero observations, a correction for continuity is applied and .5 is added to the cell entry. A warning is issued. If correct=FALSE the correction is not applied. This correction is, by default, on. It can be adjusted by specifying a smaller value. See the examples.

For correct=FALSE, the results agree perfectly with John Fox’s polycor function.

Switched to using sadmvn from the mnormt package to speed up by 50%.

**thurstone**  

*Thurstone Case V scaling*

**Description**

Thurstone Case V scaling allows for a scaling of objects compared to other objects. As one of the cases considered by Thurstone, Case V makes the assumption of equal variances and uncorrelated distributions.

**Usage**

```r
thurstone(x, ranks = FALSE, digits = 2)
```

**Arguments**

- **x**  
  A square matrix or data frame of preferences, or a rectangular data frame or matrix rank order choices.

- **ranks**  
  TRUE if rank orders are presented

- **digits**  
  number of digits in the goodness of fit

**Details**

Louis L. Thurstone was a pioneer in psychometric theory and measurement of attitudes, interests, and abilities. Among his many contributions was a systematic analysis of the process of comparative judgment (thurstone, 1927). He considered the case of asking subjects to successively compare pairs of objects. If the same subject does this repeatedly, or if subjects act as random replicates of each other, their judgments can be thought of as sampled from a normal distribution of underlying (latent) scale scores for each object, Thurstone proposed that the comparison between the value of two objects could be represented as representing the differences of the average value for each object compared to the standard deviation of the differences between objects. The basic model is that each item has a normal distribution of response strength and that choice represents the stronger of the two response strengths. A justification for the normality assumption is that each decision represents the sum of many independent inputs and thus, through the central limit theorem, is normally distributed.

Thurstone considered five different sets of assumptions about the equality and independence of the variances for each item (Thurston, 1927). Torgerson expanded this analysis slightly by considering three classes of data collection (with individuals, between individuals and mixes of within and between) crossed with three sets of assumptions (equal covariance of decision process, equal correlations and small differences in variance, equal variances).

The data may be either a square matrix of dataframe of preferences (as proportions with the probability of the column variable being chosen over the row variable) or a matrix or dataframe of rank orders (1 being preferred to 2, etc.)
Value

GF
Goodness of fit 1 = 1 - sum(squared residuals/squared original) for lower off diagonal.

Goodness of fit 2 = 1 - sum(squared residuals/squared original) for full matrix.

residual
square matrix of residuals (of class dist)

data
The original choice data

tr

Find the trace of a square matrix

Description

Hardly worth coding, if it didn’t appear in so many formulae in psychometrics, the trace of a (square) matrix is just the sum of the diagonal elements.

Usage

t(m)

Arguments

m
A square matrix

Details

The tr function is used in various matrix operations and is the sum of the diagonal elements of a matrix.

Value

The sum of the diagonal elements of a square matrix.
i.e. tr(m) <- sum(diag(m)).
**Examples**

```r
m <- matrix(1:16, ncol=4)
m
tr(m)
```

---

**Description**

Tucker and Lewis (1973) introduced a reliability coefficient for ML factor analysis. Their example data set was previously reported by Tucker (1958) and taken from Thurstone and Thurstone (1941). The correlation matrix is a $9 \times 9$ for 710 subjects and has two correlated factors of ability: Word Fluency and Verbal.

**Usage**

```r
data(Tucker)
```

**Format**

A data frame with 9 observations on the following 9 variables.

- t42 Prefixes
- t54 Suffixes
- t45 Chicago Reading Test: Vocabulary
- t46 Chicago Reading Test: Sentences
- t23 First and last letters
- t24 First letters
- t27 Four letter words
- t10 Completion
- t51 Same or Opposite

**Details**

The correlation matrix from Tucker (1958) was used in Tucker and Lewis (1973) for the Tucker-Lewis Index of factoring reliability.

**Source**

**References**

Examples

```r
data(Tucker)
fa(Tucker, 2, n.obs=710)
omega(Tucker, 2)
```

unidim  "Several indices of the unidimensionality of a set of variables."

Description

There are a variety of ways of assessing whether a set of items measures one latent trait. unidim is just one more way. If a one factor model holds in the data, then the factor analytic decomposition $F$ implies that $FF'$ should reproduce the correlations with communalities along the diagonal. In this case, the fit $FF'$ should be identical to the correlation matrix minus the uniquenesses. unidim is just the ratio of these two estimates. The higher it is, the more the evidence for unidimensionality.

Usage

```r
unidim(x, keys.list = NULL, flip = FALSE)
```

Arguments

- `x`: An input matrix or data frame. If `x` is not a correlation matrix, then the correlations are found.
- `keys.list`: If specified, then a number of scales can be tested at once. (See `scoreItems` for a similar procedure.)
- `flip`: If TRUE, then items will be keyed based upon their loadings on the first factor. Automatically done if key.list is NULL.

Details

This is an exploratory index that is still under development. A number of test cases suggest that it provides high values when the data are in fact unidimensional, low values when they are not.

The logic is deceptively simple: Unidimensionality implies that a one factor model of the data fits the covariances of the data. If this is the case, then factor model implies $R = FF' + U^2$ will have residuals of 0. Similarly, this also implies that the observed correlations will equal the model. Thus, the sum of the observed correlations (with the diagonal replaced by the communalities) should match the factor model. Compare these two models: $R - U^2$ versus $FF'$.

Value

- `uni.orig`: The raw value of the unidimensional criterion
- `uni.adj`: The unidimensional criterion when items are keyed in positive direction.
- `fit1`: The off diagonal fit from `fa`
- `alpha`: Standardized alpha of the keyed items (after appropriate reversals)
- `av.r`: The average interitem correlation of the keyed items.
- `raw.model`: The ratio of the $FF'$ model to the sum($R$)
- `adj.model`: The ratio of the $FF'$ model to the sum($R$) when items are flipped.
- `itemraw.total`: The ratio of the sum($R$ - uniqueness)/sum($R$) `itemadj.total`: Same ratio with flipped items
Note

A perhaps interesting idea but still an exploratory statistic. Treat with appropriate caution.

VSS

Apply the Very Simple Structure, MAP, and other criteria to determine
the appropriate number of factors.

Description

There are multiple ways to determine the appropriate number of factors in exploratory factor analysis. Routines for the Very Simple Structure (VSS) criterion allow one to compare solutions of varying complexity and for different number of factors. Graphic output indicates the "optimal" number of factors for different levels of complexity. The Velicer MAP criterion is another good choice. nfactors finds and plots several of these alternative estimates.

Usage

vss(x, n = 8, rotate = "varimax", diagonal = FALSE, fm = "minres",
  n.obs=NULL,plot=TRUE,title="Very Simple Structure",use="pairwise",cor="cor",...)

VSS(x, n = 8, rotate = "varimax", diagonal = FALSE, fm = "minres",
  n.obs=NULL,plot=TRUE,title="Very Simple Structure",use="pairwise",cor="cor",...)

nfactors(x,n=20,rotate="varimax",diagonal=FALSE,fm="minres",n.obs=NULL,
  title="Number of Factors",pch=16,use="pairwise", cor="cor",...)

vss
Arguments

- `x` a correlation matrix or a data matrix
- `n` Number of factors to extract – should be more than hypothesized!
- `rotate` what rotation to use ("none", "varimax", "oblimin", "promax")
- `diagonal` Should we fit the diagonal as well
- `fm` factoring method – `fm="pa"` Principal Axis Factor Analysis, `fm="minres"` minimum residual (OLS) factoring `fm="mle"` Maximum Likelihood FA, `fm="pc"` Principal Components
- `n.obs` Number of observations if doing a factor analysis of correlation matrix. This value is ignored by VSS but is necessary for the ML factor analysis package.
- `plot` `plot=TRUE` Automatically call VSS.plot with the VSS output, otherwise don’t plot
- `title` a title to be passed on to VSS.plot
- `pch` the plot character for the nfactors plots
- `use` If doing covariances or Pearson R, should we use "pairwise" or "complete cases"
- `cor` What kind of correlation to find, defaults to Pearson but see fa for the choices
- `...` parameters to pass to the factor analysis program The most important of these is if using a correlation matrix is `covmat= xx`

Details

Determining the most interpretable number of factors from a factor analysis is perhaps one of the greatest challenges in factor analysis. There are many solutions to this problem, none of which is uniformly the best. "Solving the number of factors problem is easy, I do it everyday before breakfast." But knowing the right solution is harder. (Horn and Engstrom, 1979) (Henry Kaiser in personal communication with J.L. Horn, as cited by Horn and Engstrom, 1979, MBR p 283).

Techniques most commonly used include

1) Extracting factors until the chi square of the residual matrix is not significant.
2) Extracting factors until the change in chi square from factor n to factor n+1 is not significant.
3) Extracting factors until the eigen values of the real data are less than the corresponding eigen values of a random data set of the same size (parallel analysis) `fa.parallel`.
4) Plotting the magnitude of the successive eigen values and applying the scree test (a sudden drop in eigen values analogous to the change in slope seen when scrambling up the talus slope of a mountain and approaching the rock face.
5) Extracting principal components until the eigen value < 1.
6) Extracting factors as long as they are interpretable.
7) Using the Very Simple Structure Criterion (VSS).
8) Using Wayne Velicer’s Minimum Average Partial (MAP) criterion.

Each of the procedures has its advantages and disadvantages. Using either the chi square test or the change in square test is, of course, sensitive to the number of subjects and leads to the nonsensical condition that if one wants to find many factors, one simply runs more subjects. Parallel analysis is partially sensitive to sample size in that for large samples the eigen values of random factors will be very small. The scree test is quite appealing but can lead to differences of interpretation as to when the scree "breaks". The eigen value of 1 rule, although the default for many programs, seems to be a rough way of dividing the number of variables by 3. Extracting interpretable factors means
that the number of factors reflects the investigators creativity more than the data. VSS, while very simple to understand, will not work very well if the data are very factorially complex. (Simulations suggests it will work fine if the complexities of some of the items are no more than 2).

Most users of factor analysis tend to interpret factor output by focusing their attention on the largest loadings for every variable and ignoring the smaller ones. Very Simple Structure operationalizes this tendency by comparing the original correlation matrix to that reproduced by a simplified version (S) of the original factor matrix (F). \( R = SS' + U^2 \). S is composed of just the c greatest (in absolute value) loadings for each variable. C (or complexity) is a parameter of the model and may vary from 1 to the number of factors.

The VSS criterion compares the fit of the simplified model to the original correlations: \( VSS = 1 - \text{sumsquares}(r^*)/\text{sumsquares}(r) \) where \( R^* = R - SS' \) and \( r^* \) and \( r \) are the elements of \( R^* \) and \( R \) respectively.

VSS for a given complexity will tend to peak at the optimal (most interpretable) number of factors (Revelle and Rocklin, 1979).

Although originally written in Fortran for main frame computers, VSS has been adapted to micro computers (e.g., Macintosh OS 6-9) using Pascal. We now release R code for calculating VSS.

Note that if using a correlation matrix (e.g., my.matrix) and doing a factor analysis, the parameters n.obs should be specified for the factor analysis: e.g., the call is VSS(my.matrix,n.obs=500). Otherwise it defaults to 1000.

Wayne Velicer’s MAP criterion has been added as an additional test for the optimal number of components to extract. Note that VSS and MAP will not always agree as to the optimal number.

The nfactors function will do a VSS, find MAP, and report a number of other criteria (e.g., BIC, complexity, chi square, ...)

A variety of rotation options are available. These include varimax, promax, and oblimin. Others can be added. Suggestions are welcome.

Value

A data.frame with entries: map: Velicer’s MAP values (lower values are better)
dof: degrees of freedom (if using FA)
chisq: chi square (from the factor analysis output (if using FA)
prob: probability of residual matrix > 0 (if using FA)
sqrsresid: squared residual correlations
RMSEA: the RMSEA for each number of factors
BIC: the BIC for each number of factors
eChiSq: the empirically found chi square
eRMS: Empirically found mean residual
eCRMS: Empirically found mean residual corrected for df
eBIC: The empirically found BIC based upon the eChiSq
fit: factor fit of the complete model
cfit.1: VSS fit of complexity 1
cfit.2: VSS fit of complexity 2
...
cfit.8: VSS fit of complexity 8
cresidiual.1: sum squared residual correlations for complexity 1
....: sum squared residual correlations for complexity 2 ..8

VSS.parallel

Compare real and random VSS solutions

Description

Another useful test for the number of factors is when the eigen values of a random matrix are greater than the eigen values of a a real matrix. Here we show VSS solutions to random data. A better test is probably fa.parallel.

Usage

VSS.parallel(ncases, nvariables, scree=FALSE, rotate="none")

Arguments

ncases Number of simulated cases
nvariables number of simulated variables
scree Show a scree plot for random data – see omega
rotate rotate="none" or rotate="varimax"

Value

VSS like output to be plotted by VSS.plot
VSS.plot 375

Author(s)
William Revelle

References
Very Simple Structure (VSS)

See Also
fa.parallel, VSS.plot, ICLUST, omega

Examples

#VSS.plot(VSS.parallel(200,24))

VSS.plot
Plot VSS fits

Description

The Very Simple Structure criterion (VSS) for estimating the optimal number of factors is plotted as a function of the increasing complexity and increasing number of factors.

Usage

VSS.plot(x, title = "Very Simple Structure", line = FALSE)

Arguments

x output from VSS
title any title
line connect different complexities

Details

Item-factor models differ in their "complexity". Complexity 1 means that all except the greatest (absolute) loading for an item are ignored. Basically a cluster model (e.g., ICLUST). Complexity 2 implies all except the greatest two, etc.

Different complexities can suggest different number of optimal number of factors to extract. For personality items, complexity 1 and 2 are probably the most meaningful.

The Very Simple Structure criterion will tend to peak at the number of factors that are most interpretable for a given level of complexity. Note that some problems, the most interpretable number of factors will differ as a function of complexity. For instance, when doing the Harman 24 psychological variable problems, an unrotated solution of complexity one suggests one factor (g), while a complexity two solution suggests that a four factor solution is most appropriate. This latter probably reflects a bi-factor structure.

For examples of VSS.plot output, see https://personality-project.org/r/r.vss.html
VSS.scree

Value
A plot window showing the VSS criterion varying as the number of factors and the complexity of the items.

Author(s)

VSS, ICLUST, omega

Examples
```r
test.data <- Harman74.cor$cov
my.vss <- VSS(test.data) #suggests that 4 factor complexity two solution is optimal
VSS.plot(my.vss,title="VSS of Holzinger-Harmon problem") #see the graphics window
```

---

**VSS.scree**  
*Plot the successive eigen values for a scree test*

---

Description
Cattell’s scree test is one of most simple ways of testing the number of components or factors in a correlation matrix. Here we plot the eigen values of a correlation matrix as well as the eigen values of a factor analysis.

Usage
```r
scree(rx,factors=TRUE,pc=TRUE,main="Scree plot",hline=NULL,add=FALSE)
VSS.scree(rx, main = "scree plot")
```

Arguments
- `rx`: a correlation matrix or a data matrix. If data, then correlations are found using pairwise deletions.
- `factors`: If true, draw the scree for factors
- `pc`: If true, draw the scree for components
- `hline`: if null, draw a horizontal line at 1, otherwise draw it at hline (make negative to not draw it)
- `main`: Title
- `add`: Should multiple plots be drawn?
Details

Among the many ways to choose the optimal number of factors is the scree test. A better function to show the scree as well as compare it to randomly parallel solutions is found in \texttt{fa.parallel}.

# Find the Winsorized scores, means, sds or variances for a vector, matrix, or data.frame

winsor

description

Among the robust estimates of central tendency are trimmed means and Winsorized means. This function finds the Winsorized scores. The top and bottom trim values are given values of the trimmed and 1- trimmed quantiles. Then means, sds, and variances are found.

Usage

\begin{verbatim}
winsor(x, trim = 0.2, na.rm = TRUE)
winsor.mean(x, trim = 0.2, na.rm = TRUE)
winsor.means(x, trim = 0.2, na.rm = TRUE)
winsor.sd(x, trim = 0.2, na.rm = TRUE)
winsor.var(x, trim = 0.2, na.rm = TRUE)
\end{verbatim}

Arguments

\begin{itemize}
\item \texttt{x} \hspace{1cm} A data vector, matrix or data frame
\item \texttt{trim} \hspace{1cm} Percentage of data to move from the top and bottom of the distributions
\item \texttt{na.rm} \hspace{1cm} Missing data are removed
\end{itemize}

Details

Among the many robust estimates of central tendency, some recommend the Winsorized mean. Rather than just dropping the top and bottom trim percent, these extreme values are replaced with values at the trim and 1- trim quantiles.
withinBetween

Value

A scalar or vector of winsorized scores or winsorized means, sds, or variances (depending upon the call).

Author(s)

William Revelle with modifications suggested by Joe Paxton and a further correction added (January, 2009) to preserve the original order for the winsor case.

Examples

data(sat.act)
winsor.means(sat.act) #compare with the means of the winsorized scores
y <- winsor(sat.act)
describe(y)
xy <- data.frame(sat.act,y)
#pairs.panels(xy) #to see the effect of winsorizing
x <- matrix(1:100,ncol=5)
winsor(x)
winsor.means(x)
y <- 1:11
winsor(y,trim=.5)

withinBetween

An example of the distinction between within group and between group correlations

Description

A demonstration that a correlation may be decomposed to a within group correlation and a between group correlations and these two correlations are independent. Between group correlations are sometimes called ecological correlations, the decomposition into within and between group correlations is a basic concept in multilevel modeling. This data set shows the composite correlations between 9 variables, representing 16 cases with four groups.

Usage

data(withinBetween)
**Format**

A data frame with 16 observations on the following 10 variables.

- **Group** An example grouping factor.
- **V1** A column of 16 observations
- **V2** A column of 16 observations
- **V3** A column of 16 observations
- **V4** A column of 16 observations
- **V5** A column of 16 observations
- **V6** A column of 16 observations
- **V7** A column of 16 observations
- **V8** A column of 16 observations
- **V9** A column of 16 observations

**Details**

Correlations between individuals who belong to different natural groups (based upon e.g., ethnicity, age, gender, college major, or country) reflect an unknown mixture of the pooled correlation within each group as well as the correlation of the means of these groups. These two correlations are independent and do not allow inferences from one level (the group) to the other level (the individual). This data set shows this independence. The within group correlations between 9 variables are set to be 1, 0, and -1 while those between groups are also set to be 1, 0, -1. These two sets of correlations are crossed such that V1, V4, and V7 have within group correlations of 1, as do V2, V5 and V8, and V3, V6 and V9. V1 has a within group correlation of 0 with V2, V5, and V8, and a -1 within group correlation with V3, V6 and V9. V1, V2, and V3 share a between group correlation of 1, as do V4, V5 and V6, and V7, V8 and V9. The first group has a 0 between group correlation with the second and a -1 with the third group.

*statsBy* can decompose the observed correlation in the between and within correlations. *sim.multilevel* can produce similar data.

**Source**

The data were created for this example

Yule

From a two by two table, find the Yule coefficients of association, convert to phi, or tetrachoric, recreate table the table to create the Yule coefficient.

Description

One of the many measures of association is the Yule coefficient. Given a two x two table of counts

\[
\begin{array}{c|c|c}
 & a & b \\
\hline
R1 & & \\
\hline
R2 & & \\
\hline
C1 & c & d \\
\hline
C2 & & n \\
\end{array}
\]

Yule Q is \((ad - bc)/(ad+bc)\).

Conceptually, this is the number of pairs in agreement (ad) - the number in disagreement (bc) over the total number of paired observations. Warren (2008) has shown that Yule’s Q is one of the “coefficients that have zero value under statistical independence, maximum value unity, and minimum value minus unity independent of the marginal distributions” (p 787).

\(ad/bc\) is the odds ratio and \(Q = (OR-1)/(OR+1)\).

Yule’s coefficient of colligation is \(Y = (\sqrt{OR} - 1)/(\sqrt{OR}+1)\). \(Yule.inv\) finds the cell entries for a particular Q and the marginals \((a+b,c+d,a+c, b+d)\). This is useful for converting old tables of correlations into more conventional phi or tetrachoric correlations \(tetra\). \(Yule2phi\) and \(Yule2tetra\) convert the Yule Q with set marginals to the corresponding phi or tetrachoric correlation.

Bonett and Price show that the Q and Y coefficients are both part of a general family of coefficients raising the OR to a power (c). If \(c=1\), then this is Yule’s Q. If \(c=.5\), then Yule’s Y. If \(c = .75\), then this is Digby’s H. They propose that \(c = .5 - (.5 * \text{min(cell probability})^2\) is a more general coefficient. \(YuleBonett\) implements this for the 2 x 2 case, \(YuleCor\) for the data matrix case.

Usage

\begin{verbatim}
YuleBonett(x, c=1, bonett=FALSE, alpha=.05) \#find the generalized Yule coefficients
YuleCor(x, c=1, bonett=FALSE, alpha=.05) \#do this for a matrix
Yule(x, Y=FALSE) \#find Yule given a two by two table of frequencies
\#find the frequencies that produce a Yule Q given the Q and marginals
Yule.inv(Q,m,n=NULL) \#find the phi coefficient that matches the Yule Q given the marginals
Yule2phi(Q,m,n=NULL) \#YuleBonett(x, c=1, bonett=FALSE, alpha=.05)
Yule2tetra(Q,m,n=NULL, correct=TRUE)
\end{verbatim}
Yule2poly(Q,m,n=NULL,correct=TRUE)

Arguments

x  A vector of four elements or a two by two matrix, or, in the case of YuleBonett or YuleCor, this can also be a data matrix
c  l returns Yule Q, .5, Yule’s Y, .75 Digby’s H
bonett  If FALSE, then find Q, Y, or H, if TRUE, then find the generalized Bonett coefficient
alpha  The two tailed probability for confidence intervals
Y  Y=TRUE return Yule’s Y coefficient of colligation
Q  Either a single Yule coefficient or a matrix of Yule coefficients
m  The vector c(R1,C2) or a two x two matrix of marginals or a four element vector of marginals. The preferred form is c(R1,C1)
n  The number of subjects (if the marginals are given as frequencies
correct  When finding a tetrachoric correlation, should small cell sizes be corrected for continuity. See (link{tetrachoric} for a discussion.

Details

Yule developed two measures of association for two by two tables. Both are functions of the odds ratio

Value

Q  The Yule Q coefficient
R  A two by two matrix of counts
result  If given matrix input, then a matrix of phis or tetrachorics
rho  From YuleBonett and YuleCor
ci  The upper and lower confidence intervals in matrix form (From YuleBonett and YuleCor).

Note

Yule.inv is currently done by using the optimize function, but presumably could be redone by solving a quadratic equation.

Author(s)

William Revelle
